where P is the pressure, T is the temperature in kelvin, ρ is the density, $R = 8.314472 \text{ J mol}^{-1} \cdot \text{K}^{-1}$ is the universal gas constant, and $B(T)$ and $C(T)$ are the second and third density virial coefficients. The virial coefficients B and C and their derivatives for gaseous N_2O recommended by NIST are tabulated in Table 7 along with other physical properties. The density virial coefficients were derived from velocity of sound measurements [54].

3.1.6 Velocity of Sound in Gaseous Nitrous Oxide

The velocity of sound was measured in gaseous nitrous oxide and nitric oxide using an acoustic resonance technique over the temperature range from 200 to 460 K and at pressures up to the lesser of 1.6 MPa or 80% of the vapor pressure [54]. All measurements were above the triple point temperature of N_2O . The data were analyzed to ob-

Figure 7: Isotherms of the velocity of sound of gaseous nitrous oxide. (Created by Schmidt 2016, based on data from [54].)

tain the constant-pressure ideal-gas heat capacity C_p^0 as a function of temperature. For N_2O , the values of C_p^0 agreed within 0.1% with those determined from spectroscopic data. The velocity-of-sound data were fitted by virial equations of state to obtain temperature-dependent density virial coefficients. In trying to explain what caused the variation from ideal gas behavior, two virial coefficient models were employed, one based on square-well intermolecular potentials, and the second based on a hard-core Lennard-Jones intermolecular potential. The model reproduced nearly all the sound velocity data to within $\pm 0.01\%$ and may be used to calculate vapor densities. Figure 7 shows isotherms for the velocity of sound of gaseous nitrous oxide at pressures above the triple point and below the critical point.

3.1.7 Vapor Pressure of Nitrous Oxide

Vapor pressure data reported in the literature during the first half of the twentieth century were spread over a wide range and were often inconsistent. An early report [27] gave the following Antoine equation for the vapor pressure of N_2O between 184 and 240 K:

$$\log P = 4.1375 - \frac{656.60}{T - 26}$$

where P is the pressure in atm, and T is the temperature in kelvin. A renewed measurement between 243 and 309 K (-30 and $+36^\circ\text{C}$) [33] gave the following curve fitted equation for the vapor pressure as a function of temperature:

$$\log P = 4.1375 - \frac{656.60}{T - 26}$$

where P is the pressure in atm, and T is the temperature in kelvin. This equation was graphed in Figure 8 from a spreadsheet. The vapor pressure of nitrous oxide at room temperature ($20^\circ\text{C} = 68^\circ\text{F} = 293\text{ K}$) is 49.9 atm (733 psia).

The vapor pressure data reported by Cook [34] are in good agreement with the Couch and Kobe [33] later set of data, although just a bit higher. Cook had determined the vapor pressure of nitrous oxide only over a very narrow range from 285 K (12°C) to the critical point, and the vapor pressure was expressed by the following equation:

$$\log P = 4.6258 - \frac{858.63}{T}$$

where P is the vapor pressure in atm, and T is the temperature in kelvin. The Cook [34] data also agreed well with earlier data reported by Michels et al. [57] and Villard [58]. The vapor pressure data collected by Stull [59] for the temperature range 129.8–

Figure 8: Vapor pressure of nitrous oxide. (Image created by Schmidt 2020, based on data from [33].)

187.7 K have been converted to an Antoine equation and posted on the NIST Chemistry WebBook web site [43]:

$$\log P = A - \left(\frac{B}{T + C} \right)$$

where P is the vapor pressure in bar, T is the temperature in kelvin, and A, B, C are constants: $A = 4.37799$, $B = 621.077$, $C = -44.659$. The data generated from this equation are shown in Figure 9:

Figure 9: Vapor pressure of nitrous oxide. (Chart created by Schmidt 2016, based on data from [59].)

Saturated vapor pressures were measured in an isochoric apparatus over the temperature range from 219 to 273 K as part of an overall PVT characterization including both two-phase saturated pressure and superheated gas-phase above atmospheric pressure conditions [45]. The raw (unsmoothed) data are tabulated in Table 8 and illustrated in Figure 10.

Data source: [45]

Figure 10: Vapor pressure of nitrous oxide. (Image created by Schmidt 2020, based on data from [45].)

In order to compare the experimental data to previously published literature data, 146 data points from a total of 11 different data sources were examined, and 27 were rejected as outliers, leaving 119 data points to be curve fitted by regression analysis with a Wagner equation in the form:

$$\ln \frac{P}{P_c} = \frac{T_c}{T} [A_1\tau + A_2\tau^{1.5} + A_3\tau^{2.5}]$$

where $\tau = (T_c - T)/T_c$; T_c = critical temperature $T_c = 309.54$ K, P_c critical pressure = 7249.27 kPa and A_1 , A_2 , and A_3 are constants: $A_1 = -6.88269266$, $A_2 = 1.94458967$, and $A_3 = -2.58663757$.

A set of data from multiple literature sources covering a very wide pressure range is shown in Figure 11 copied from Reference [60]. The vapor pressure of N_2O calculated from molecular orbital theory was compared with the experimental data in Figure 25 (Section 3.4.5) [61].

The triple point pressure was given as 0.87890 ± 0.0001 bar (Fonseca and Lobo [62]) bar or 0.8791 ± 0.00008 bar (Calado, Rebelo et al. [63]), as quoted by NIST Chemistry WebBook [43].

Vapor pressure data from 9 different sources, including 296 experimental points collected during a time span from 1935 to 2007, were critically evaluated and combined into a uniform data format, giving the following Wagner vapor pressure equation [30]:

$$P = P_c \exp \left[\frac{(a_1\tau + a_2\tau^{1.5} + a_3\tau^{2.5} + a_4\tau^5)}{(T/T_c)} \right]$$

Figure 11: Vapor pressure of nitrous oxide. (Reproduced and modified from [20].)

where P is the vapor pressure in kPa, P_c is the critical pressure in kPa, T is the temperature in kelvin, $\tau = (1 - T/T_c)$, $a_1 = -6.8657$, $a_2 = 1.9373$, $a_3 = -2.6440$, and $a_4 = 0.0387$. In this equation, if one sets $T = T_c$, the critical pressure is $P_c = 7243$ kPa. For $P = 101$ kPa, the normal boiling point is $T_b = 184.646$ K. Because the vapor pressure at the triple point of frozen nitrous oxide is relatively high, and because the liquidus range is so narrow, sublimation of nitrous oxide going directly from the frozen to the vapor state is a likely occurrence. Sublimation pressure data from 7 different sources taken between 1930 and 1983 were combined into one data set of 160 data points and curve fitted to the equation

$$\ln P = \ln P_t + \frac{(e_1\theta + e_2\theta^f)}{(T/T_t)}$$

where P is the sublimation pressure, T_t is the triple point temperature in kelvin, p_t is the triple point pressure in Pascal, $\theta = (1 - T/T_t)$, and e_1 , e_2 and f are numerical adjustable parameters. These parameters are: $e_1 = -6.6551$, $e_2 = -9.8076$, and $f = 1.0364$. The relative average absolute deviation for this curve-fitting exercise was AAD = 4% (in the pressure). The enthalpy of sublimation at the triple point can be calculated by adding the enthalpy of fusion and the enthalpy of evaporation, which resulted in an estimate of 23.205 kJ/mol. A maximum value of the enthalpy of sublimation occurs at $T = 50$ K where it is 25.214 kJ/mol. The sublimation pressure curve occupies the lower 3/4 and the major portion of the phase diagram Figure 12, which shows the pressure versus temperature phase boundary diagram for all three states. This graph is a compilation of data from about 15 different sources from the literature.

Based on sublimation pressure measurements, the entropy of solid N_2O at 0 K was calculated as $S_0 = 5.98 \text{ J mol}^{-1} \text{ K}^{-1} = 1.43 \text{ cal mol}^{-1} \text{ K}^{-1}$, and the enthalpy of solid N_2O at 0 K was predicted as $H_0 = -24.2 \text{ kJ/mol} = -5799 \text{ cal/mol}$ [64].

Fractionated distillation of NO has been used for isotope separation for production of ^{15}N , and the question was whether or not a similar isotope effect has industrial application, but the difference in vapor pressures of N_2O isotopes is less pronounced and most likely cannot be used for ^{15}N production. The vapor pressures of three isotopic samples of N_2O enriched in ^{15}N and ^{18}O were compared with normal N_2O over the temperature range 143–219 K [65]. Over the temperature range studied in the solid and in the liquid in the neighborhood of the triple point, the vapor pressures decreased in the order $^{14}\text{N}_2^{16}\text{O} \geq ^{14}\text{N}^{15}\text{N}^{16}\text{O} \geq ^{15}\text{N}^{14}\text{N}^{16}\text{O} \geq ^{14}\text{N}_2^{18}\text{O}$. Shifts in the internal stretching and bending modes on condensation lead to significant differences in the vapor pressures of the isomers $^{15}\text{N}^{14}\text{N}^{16}\text{O}$ and $^{14}\text{N}^{15}\text{N}^{16}\text{O}$.

The vapor pressure of solid nitrous oxide in the range 146–182.4 K (triple point) can be expressed in the form of an Antoine equation

$$\log_{10} P = -\frac{1270.42}{T} + 8.955644 - 00094121 \times T$$

Figure 12: Phase diagram of nitrous oxide. (Republished and modified from [30], with permission of © 2009 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

where P is the pressure in pascal, and T is the temperature in kelvin. The vapor pressure of liquid nitrous oxide in the range 182.4 K (triple point) to 185 K can be expressed by the equation

$$\log P = -\frac{886.293}{T} + 9.803215$$

where P is the pressure in pascal, and T is the temperature in kelvin [23]; see also References [66] and [22].

3.1.8 Viscosity of Nitrous Oxide

3.1.8.1 Viscosity of Gaseous Nitrous Oxide

The viscosity of gaseous nitrous oxide was measured in the temperature range of 373 to 1273 K (100–1000 °C) using a specially constructed transpiration apparatus of fused

silica [67]. Results at the lower temperatures showed good agreement with previously published data, with the viscosity behaving normally up to about 823 K (550 °C), above which the thermal decomposition of nitrous oxide became noticeable, and viscosity measurements became erratic.

Eight sets of experimental viscosity data were taken from the pre-1975 literature and combined into a recommended data set [55]. Graphing the departure of the individual data from the averaged result showed a very irregular pattern, and deviations went in all directions and at all temperatures. The recommended viscosity data for the lower temperature range are summarized in Table 9. The upper temperature data were omitted from this table because they were adulterated by incipient decomposition.

The viscosity and thermal conductivity coefficients of gaseous nitrous oxide and nitrous oxide/carbon dioxide mixtures were calculated for a temperature range 180–900 K and pressures from 0.1 to 23 MPa based on theoretical considerations and the theorem of corresponding states [68]. The viscosity at low pressures as a function of temperature was expressed by a polynomial equation with nine coefficients. The viscosity at 273 K and 101 kPa was predicted as $0.74250 \times 10^{-4} \text{ lb}_m \text{ ft}^{-1} \text{ s}^{-1} = 0.11 \text{ cPs}$. For comparison, data were also offered for $\text{N}_2\text{O}/\text{CO}_2$ mixtures containing 6 or 12% CO_2 .

The dynamic viscosity of gaseous nitrous oxide was measured at atmospheric pressure in the temperature range 300.6–473 K (27.5–200 °C) with an accuracy of $\pm 0.2\%$ [69]. The results can be correlated by a law of corresponding states.

The dynamic viscosity of gaseous nitrous oxide in the temperature range 190 to 310 K can be expressed by the equation

$$\ln \eta = A \ln T + \frac{B}{T} + \frac{D}{T^2} + D$$

where η is the dynamic viscosity in μPs ($1 \mu\text{Ps} = 10^{-7} \text{ kg m}^{-1} \text{ s}^{-1}$), T is the temperature in kelvin, and A , B , C , and D are constants as follows: $A = 0.224485$, $B = -375.3232$, $C = 22927.27$, and $D = 4.721$ [70].

The viscosities of gaseous nitric oxide (372–1015 K) and nitrous oxide (372–733 K) have been measured using a capillary-flow viscometer in a comparative mode, calibrating the instrument with nitrogen gas [71]. Smoothed viscosity data for nitrous oxide are shown in Table 10.

The viscosity of nitrous oxide as a function of temperature can be expressed by the equation

$$\eta = \frac{aT^{1/2}}{1 + b/T + c/T^2}$$

where η is the viscosity in $\mu\text{N s m}^{-2}$, T is the temperature in kelvin, and a , b , and c are constants: $a = 2.064 \mu\text{N s m}^{-2} \text{ K}^{-1/2}$, $b = 597.2 \text{ K}$, and $c = -62380 \text{ K}^2$.

The transport properties of gases in the limit of zero density provide a basis for the prediction of these properties over a wider range of thermodynamic states. In order to extend studies on the viscosity of polyatomic gases to nitrous oxide and to provide

a background for a description of the thermal conductivity of these gases, nitrous oxide viscosity data were correlated by kinetic theory [72].

The viscosity of gaseous nitrous oxide was measured with an oscillating-disk viscometer in the critical region between 309.65 and 318.15 K and pressures up to 9.6 MPa [44]. The viscosity of N_2O exhibited an anomalous increase near the critical point. The anomalous increase in viscosity as the temperature approached the critical point also caused more data scatter and was analyzed with a viscosity equation proposed by

Table 10: Smoothed dynamic viscosity data for gaseous nitrous oxide.

Busu and Sengers, which was supposed to be able to predict viscosity based on known critical point properties. Figure 13 shows the viscosity as a function of pressure, and Figure 14 shows the same data as a function of density.

Figure 13: Dynamic viscosity of gaseous N₂O as a function of pressure. (Republished and modified from [44], with permission from © 1994 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

Figure 14: Dynamic viscosity of gaseous N_2O as a function of density. (Republished and modified from [44], with permission from © 1994 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

Measurements of the viscosity of gaseous nitrous oxide using the same oscillating disk viscometer were then extended to pressures up to 25 MPa and temperatures from 298.15 to 398.15 K [73]. Historical data from 12 previously reported viscosity measurements going back all the way to 1909 were reviewed, and Figure 15 shows the results of plotting the investigator's own viscosity data as a function of pressure and temperature, which showed a substantial difference between the more recent measurements and literature data (dotted lines) from 1975 [74].

Figure 15: Plots of dynamic viscosity as a function of pressure P for gaseous nitrous oxide for five different temperatures. (Reprinted and modified from [73] with permission from © 1996 American Chemical Society; permission conveyed through RightsLink.)

The experimental results were fitted to an empirical equation that gives the viscosity of N_2O at 101 kPa as a function of temperature:

$$\eta = \frac{(T/\text{K})^{0.5}}{a_1} + \frac{a_2}{(T/\text{K})} + \frac{a_3}{(T/\text{K})^2} + \frac{a_4}{(T/\text{K})^3}$$

where η is the viscosity in $\mu\text{Pa s}$, T is the absolute temperature in kelvin, and a_n ($n=1-4$) are constants: $a_1 = 0.5992$, $a_2 = 0.1770 \times 10^3$, $a_3 = -0.2413 \times 10^4$, and $a_4 = -0.7192 \times 10^6$.

The viscosity and velocity of sound of gaseous nitrous oxide were measured using a Greenspan acoustic viscometer over the temperature range 225–375 K and pressures up to 3.4 MPa [56]. The viscosity isotherms are graphed in Figure 16. The velocity of sound data measured up to 3.4 MPa were fitted by a virial equation of state that predicted gas densities within the uncertainties of the equations of states available in the literature. The velocity of sound data were similar to those already described in Section 3.1.5. Measurements of the velocity of sound in N_2O have been reported previously but only at pressures up to 1.5 MPa. The Hurly [56] measurements agreed with these earlier literature values with maximum relative standard deviations of only 0.025%.

Figure 16: Viscosity isotherms of gaseous nitrous oxide. (Created by Schmidt 2020, based on data from [56].)

From these data a graph showing the viscosity of nitrous oxide gas at atmospheric pressure as a function of temperature can be constructed (Figure 17).

3.1.8.2 Viscosity of Liquid Nitrous Oxide

Because N_2O has such a narrow liquid range, not many measurements of physical properties of the liquid were made in this range.

3.1.8.3 Viscosity of Gas Mixtures Containing Nitrous Oxide

Mixing nitrous oxide with other gases might bring some advantages: dilution with inert gases would reduce the tendency for detonations, mixing with other oxidizers might improve the performance as an oxidizer in rocket engines or lower the freezing point, and mixing with gaseous fuels would increase the performance as a gaseous monopropellant (but may widen the detonable range).

Figure 17: Viscosity of gaseous nitrous oxide at atmospheric pressure. (Created by Schmidt 2020, based on data from NIST.)

The viscosity and diffusion coefficient of binary gaseous systems of nitrous oxide with N_2 , Ar, and CO_2 in the range of temperatures from 298 to 473 K (25 to 200 °C) were measured, and the calculated values of the binary mixtures diffusion coefficients were consistent with the KRW Law of Corresponding States [75]. The viscosity of N_2O/CO_2 mixtures containing 6 or 12% CO_2 was calculated based on the theorem of corresponding states [68].

The viscosity of mixtures of nitrous oxide with nitric oxide was measured between 474 and 788 K (201 and 515 °C) for mixtures containing 25, 50, or 75 vol-% nitric oxide [76]. The results are summarized in Table 11.

Mixtures of nitrous oxide and ammonia have been evaluated as gaseous monopropellants. It is, therefore, of interest to find data for the viscosity of gaseous N_2O/NH_3 mixtures taken with a capillary viscometer at three different temperatures 298, 308, and 353 K (25, 35, and 80 °C) [77]. The dynamic viscosities of N_2O/NH_3 mixtures at 308 K (35 °C) are illustrated in Figure 18. The unit of viscosity used here is ($10^7 \text{ g cm}^{-1} \text{ s}^{-1}$); $1.0 \text{ g cm}^{-1} \text{ s}^{-1}$ corresponds to 100 cPs. For comparison, the values for N_2O by itself (without NH_3) were $1486 \times 10^{-7} \text{ g cm}^{-1} \text{ s}^{-1}$ at 298 K, $1533 \times 10^{-7} \text{ g cm}^{-1} \text{ s}^{-1}$ at 308 K, and $1730 \times 10^{-7} \text{ g cm}^{-1} \text{ s}^{-1}$ at 353 K. It appears that the investigators were unaware of the explosive potential of such oxidizer/fuel mixtures. The solid and dashed lines are predictions from theory. The solid circles are measured data points.

3.1.9 Surface Tension of Liquid Nitrous Oxide

The average of three determinations of surface tension of liquid nitrous oxide at the boiling point (183.75 K = -89.4 °C at an atmospheric pressure of 741.1 mm Hg) was $26.323 \times 10^{-5} \text{ N/cm}$ [35]; see also Reference [78].

The surface tension of liquid nitrous oxide was measured between 182 and 184 K, which is between the freezing point and the boiling point of the liquid at atmospheric pressure, by a capillary rise method where three capillaries with different diameters (0.2, 0.4, and 2 mm) were interconnected and partially filled with liquid [31]. The data are listed in Table 12.

3.2 Thermal Conductivity and Heat Transfer Properties of Nitrous Oxide

The thermal conductivity of gaseous nitrous oxide goes through a minimum near 330 K (Figure 19). The thermal conductivity of gaseous nitrous oxide listed on the NIST Chemistry WebBook website is tabulated in Table 13 and illustrated in Figure 20.

Gaidei [2] quoted the thermal conductivity of liquid (λ_{liquid} , $\text{W m}^{-1} \text{K}^{-1}$) and gaseous (λ_{gas} , $\text{W m}^{-1} \text{K}^{-1}$) nitrous oxide on the line of saturation at different temperatures from an unidentified source as listed in Table 14. They should have listed the pressures at which these measurements were taken.

The thermal conductivities of two binary systems of non-polar gases, $\text{N}_2/\text{N}_2\text{O}$ and $\text{NO}/\text{N}_2\text{O}$, were measured in the temperature range from 323 to 453 K (50 to 180 °C) [79]. It was found that the presence of NO in N_2O effectively increased the rate of its catalytic decomposition on Fe-ZSM-5 zeolite, and at the same time the NO, CO_2 , and water inhibited the process of homogeneous N_2O decomposition.

Attempts to predict the thermal conductivity of polyatomic gases have not always been successful. Extending the theory to include polyatomic gases having more than one relaxation time showed that in the case of CO_2 , all theories matched equally well with experimental results, while for N_2O there was a poor fit and a different mathematical expression had to be used [80].

The thermal conductivity of gaseous N_2O measurements by Johnston and Grilly [81] were included for comparison in a later graph (Figure 21) created by Richter and Sage [82]. The Johnston and Grilly data tended to be a bit higher than the Richter and

Sage data. Table 15 lists the thermal conductivity of gaseous nitrous oxide in comparison to those of nitric oxide and dioxygen.

The thermal conductivity of gaseous nitrous oxide was measured at temperatures from 278 to 444 K (40 to 340 °F) and at pressures up to 34.5 MPa (5000 psia) using an apparatus consisting of two concentric spheres where the fluid under study filled a narrow gap between the two spheres, and the inner sphere was heated electrically and the temperature difference between the two spheres was measured [82]. The thermal conductivity of nitrous oxide at atmospheric pressure is illustrated in Figure 21, and the thermal conductivity at elevated pressures is illustrated in Figure 22.

Experimental measurements of the thermal conductivity of gaseous nitrous oxide were reported for pressures up to 5.343 MPa (775 psia) at 323 K (122 $^{\circ}\text{F}$) [83].

The thermal conductivity of nitrous oxide was measured by the conductivity column method in the temperature range 323 to 1173 K (50 to 900 $^{\circ}\text{C}$) [84]. The data suggested that it is necessary to take into account the relaxation of translational-internal

energy exchange for nitrous oxide in this temperature range for an adequate theoretical interpretation of its thermal conductivity.

The viscosity and thermal conductivity coefficients of gaseous nitrous oxide and nitrous oxide/carbon dioxide mixtures were calculated for a temperature range 180–900 K (330–1600 R) and pressures from 0.1 to 23 MPa (3500 psi) based on theoretical considerations and the theorem of corresponding states [68]. The thermal conductivity at low pressures as a function of temperature was expressed by a polynomial equation with nine coefficients. The thermal conductivity at 273 K and 101 kPa was predicted as $0.584 \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1} = 0.0024 \text{ cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1} = 0.010 \text{ W cm}^{-1} \text{ °C}^{-1}$. Data were also offered for $\text{N}_2\text{O}/\text{CO}_2$ mixtures containing 6 or 12% CO_2 .

Absolute measurements of the thermal conductivity of nitrous oxide were carried out with a transient hot-wire instrument in the temperature range 308 to 430 K and at pressures up to 11 MPa [85]. For nitrous oxide near its critical conditions, the accuracy of measurements was degraded, and the data spread may be as bad as $\pm 2\%$.

The thermal conductivity coefficient of solid N_2O exhibited a surprisingly (compared with simple molecular crystals such as N_2 , CO , or O_2) high value in the temperature range 1.2,40 K, and temperature dependence of the thermal conductivity was determined at temperatures below 23 K [86]. This indicated that relatively low density of dislocations and weak phonon-phonon interaction might be reasons for the good thermal conduction in solid N_2O . The influence of possible low-temperature dipolar ordering on thermal conductivity of nitrous oxide crystal is uncertain, see also Reference [87].

The preferred method for warming liquid nitrous oxide and to prevent it from freezing is to fill a run tank with sufficient ullage volume and allow it to slowly warm up to the desired temperature by circulation of ambient air around the tank. If a faster active heating system must be used, such as for testing in colder climates during the winter, one can run the nitrous oxide through a heat exchanger with a uniform wall temperature such as a coil submerged in a water bath. One must never expose nitrous oxide lines, tanks or components to open flames or other concentrated heat sources. Hot spots in heat exchangers can lead to catastrophic failures even with liquid flow. SpaceDev has conducted several tests on nitrous oxide heat exchangers in association with Purdue University and has demonstrated that it is possible to start a decomposition reaction with liquid nitrous oxide in tubing under a 1/4-in. diameter by exposing it to an extreme, highly concentrated heat source [88]. This should be a warning to all designers working on the design of nitrous oxide feed systems.

3.3 Thermodynamic Properties of Nitrous Oxide

The thermodynamic properties of nitrous oxide were examined in a doctoral dissertation [50].

3.3.1 Heat Capacity of Nitrous Oxide

The heat capacity of gaseous nitrous oxide at 298 K is $38.617 \text{ J mol}^{-1} \text{ K}^{-1}$. The heat capacity of gaseous nitrous oxide as a function of temperature can be calculated from the following polynomial equation

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + \frac{E}{\tau^2}$$

where C_p is the molar heat capacity in $\text{J mol}^{-1} \text{ K}^{-1}$, τ is the temperature in kelvin divided by 1000, and A, B, C, D, and E are constants listed in Table 16 for two different temperature ranges. One must note that N_2O is unstable at temperatures above 700 K, and the column for the higher temperature range 1100–6000 K is only of academic value. It is not very practical to list thermodynamic data for a compound that is unstable at

Table 16: Thermodynamic property polynomial equation coefficients for gaseous nitrous oxide.

Temperature, K	298–1400	1400–6000
<i>A</i>	27.67988	60.30274

Data source: [43, 89]

the temperature range listed. It would be much more valuable to have more accurate thermodynamic data for liquid nitrous oxide; see also Reference [22].

The heat capacity of solid and liquid nitrous oxide was measured with an adiabatic calorimeter between 1.9 and 184 K [23]. The anomalous increase of heat capacity below the triple point was interpreted as arising from thermal creation of orientational defects with an enthalpy of formation of 10.8 kJ/mol. The molar heat capacity as a function of temperature is shown in Figure 23, a graph that uses two different scale expansions (which may be confusing at the first glance). Smoothed and interpolated heat capacity of solid nitrous oxide are listed in Table 17.

**Figure 23:** Molar heat capacity of nitrous oxide as a function of temperature. (Reproduced and modified from [23], with permission of Chemical Society of Japan.)

3.3.2 Enthalpy of the Formation of Nitrous Oxide

Enthalpy of formation data reported for nitrous oxide in the literature are summarized in Table 18.

Table 18: Enthalpy of formation of nitrous oxide.

Physical state	SI Units	Other units	References
Gas at 298 K	+82.048 kJ/mol	+19.6 kcal/mol	[43]
Gas at 298 K	+82.048 kJ/mol	+19.61 $\pm$ 0.1 kcal/mol	[89]
Liquid at 298 K	+75.595 kJ/mol	+18.068 kcal/mol	
Liquid at NBP	+65 kJ/mol	+15.53 kcal/mol	[90]

The standard enthalpy of formation of N_2O gas is $\Delta H_{\text{f,gas}}^\circ = +82.05 \text{ kJ/mol} = +19.6 \text{ kcal/mol}$ [43]. Note that the enthalpy of formation is highly positive, which

means that nitrous oxide can spontaneously decompose back to the elements from which it was formed and this would be a very exothermic reaction, quite suitable for its proposed use as a monopropellant. The enthalpy of formation of gaseous nitrous oxide as a function of temperature can be calculated from the following polynomial equation

$$\Delta H = H^\circ - H_{298.15}^\circ = A \times \tau + \frac{B \times \tau^2}{2} + \frac{C \times \tau^3}{3} + \frac{D \times \tau^4}{4} - \frac{E}{\tau} + F - H$$

where ΔH is the enthalpy in kJ/mol, τ is the temperature in kelvin divided by 1000, and A, B, C, D, E, F, and H are constants listed in Table 16 above for two different temperature ranges.

The latent heat of vaporization of N_2O at 298 K is 6.455 kJ/mol. Subtracting this from the enthalpy of formation of gaseous N_2O at 298 K (+82.05 kJ/mol) gives the enthalpy of formation of liquid N_2O at 298 K: +75.595 kJ/mol, which is the value we entered into Table 18 above.

3.3.3 Heat of Fusion of Nitrous Oxide

The molar enthalpy of fusion of nitrous oxide at the triple point derived from a Simon equation [30] is 6.720 kJ/mol, which can be compared with the measured enthalpy of fusion of 6.529 kJ/mol, which is the average of the two values reported in the literature [22, 23].

From another source, Gaidei [2] quoted the heat of fusion as $\Delta H_{\text{fus}} = 6.54$ kJ/mol. The heat of fusion at atmospheric pressure was found to be 6.516 ± 0.02 kJ/mol, and the entropy of fusion was 35.7 ± 0.1 J K⁻¹ mol⁻¹ [23].

3.3.4 Heat of Evaporation of Nitrous Oxide

The heat of evaporation of nitrous oxide at the moment one withdraws propellant from a self-pressurizing propellant tank containing liquid N_2O , is the key parameter entering a model that predicts the pressure and temperature history of liquid in a tank that relies on its own vapor pressure for expulsion. Other propellants or working fluids in this category that have been used are propane and propylene. In the case of nitrous oxide, due to its narrow liquidus range, the concern is that one might accidentally withdraw so much propellant that the contents in the tank will freeze. In order to prevent freezing, heat must be supplied from somewhere else in the system. Either the tank has to be wrapped in an electric heating blanket, or, as long as the satellite is in direct sunlight, the albedo of the sun-facing side of the satellite can be controlled by black and white louvers to allow the tank to warm back up. One of the first determinations of the heat of evaporation of N_2O [22] found the latent heat of evaporation to be 3958 ± 3 cal/mol, which converts to 16.56 kJ/mol, similarly to what was found by later investigators.

One of the more accurate determinations of the heat of evaporation of N_2O at the normal boiling point ($184.695\text{ K} = -88.465^\circ\text{C}$) measured the latent heat as $16.55\text{ kJ/mol} = 3.95\text{ kcal/mol}$ [27].

From the vapor pressure data in Figure 8, an equation was derived that gives the latent heat of vaporization as a function of the temperature [50, 33]:

$$\Delta H_{\text{evap}} = a(t_c - t)^b + c(t_c - t) + r_v$$

where ΔH_{evap} is the heat of evaporation in cal/g, t_c is the critical temperature = 36.434°C , t is the temperature in $^\circ\text{C}$, r_v is a residual correction, and a , b , and c are constants: $a = 12.9922$, $b = 0.417796$, $c = -0.082167$. Experimental and smoothed data calculated from this equation are summarized in Table 19 and illustrated in Figure 24.

Table 19: Vapor pressure and heat of evaporation of nitrous oxide.

Data source: [33]

The heat of evaporation of nitrous oxide at normal boiling point of 184.81 K and 101.7 kPa was found to be $16.544 \pm 0.020\text{ kJ/mol}$ [23], which is very similar to a value reported earlier in the literature [22] of $16.564 \pm 13\text{ kJ/mol}$ at 184.59 K .

Figure 24: Heat of vaporization of nitrous oxide. (Created by Schmidt 2020, based on data from [33].)

The calculated heat of evaporation of N_2O was compared with experimental data in Figure 26 (Section 3.4.5) [61].

The sudden accidental freezing of liquid N_2O during rapid discharge from an airborne tank and clogging of discharge orifices would prevent the aircraft from dumping the unwanted mass in order to reduce its touchdown mass. The freezing of flowing N_2O has been studied in several oxidizer dump tests [91, 92].

Gaidei [2] quoted the following from other sources: $\Delta H_{\text{evap}} = 16.55 \text{ kJ/mol}$ and heat of liquid nitrous oxide evaporation on the line of saturation at different temperatures: at $T = 260 \text{ K}$ (-13°C) 11.58 kJ/mol ; at $T = 295 \text{ K}$ (22°C) 7.30 kJ/mol ; at $T = 305 \text{ K}$ (32°C) 4.75 kJ/mol .

3.3.5 Entropy of Nitrous Oxide

The entropy of gaseous N_2O at 298 K and 1 atm pressure is $S^\circ_{\text{gas}} = 219.96 \text{ J mol}^{-1} \text{ K}^{-1}$ (NIST 1998). The entropy of gaseous N_2O can be calculated from the polynomial equation

$$S^\circ = A \times \ln(\tau) + B \times \tau + \frac{C \times \tau^2}{2} + \frac{D \times \tau^3}{3} - \frac{E}{(2 \times \tau^2)} + G$$

where G is the integration constant in $\text{J mol}^{-1} \text{ K}^{-1}$, τ is the temperature in kelvin divided by 1000, and A , B , C , D , E , and G are constants listed in Table 16 for two different temperature ranges.

3.4 Molecular Structure of Nitrous Oxide

Nitrous oxide (dinitrogen monoxide) can exist in three isomeric forms: an asymmetric linear form NNO, a symmetric linear form NON, and a cyclic triangular form. All measurements support the asymmetric linear form, although computations also indicate the possibility of other forms as short-lived intermediates. Although N_2O has no inversion symmetry, it has been shown to oscillate between two resonant structures with opposing dipole moments, in effect canceling each other

As a result, the net dipole moment of N_2O is negligible compared to its substantial quadrupole moment. The linear shape of the N_2O molecule has a pronounced effect on the collision cross section of N_2O in molecular beams at low pressures.

3.4.1 Bond Lengths and Bond Angles of the N_2O Molecule

The N—N bond (1.128 Å) in nitrous oxide is substantially shorter than the standard N=N bond (e.g., 1.24 Å in $\text{MeN}=\text{NMe}$) and is only insignificantly longer than the $\text{N}\equiv\text{N}$ bond (1.10 Å, N_2). The N—O bond (1.184 Å, N_2O) is quite similar to the standard N=O double bond (1.21 Å, $\text{MeN}=\text{O}$). Therefore, the N—N and N—O bond orders in nitrous oxide are estimated at 2.73 and 1.61, respectively.

3.4.2 Crystal Structure of Frozen Nitrous Oxide

For rocket applications, the rocket engineer would rather not see frozen nitrous oxide clogging the feed lines at any time, but the crystal structure of frozen nitrous oxide is one of the reasons for the narrow liquid range of this oxidizer.

A comparison of Raman ν_1 line intensities expected for a random distribution of the molecular orientations N—N—O and O—N—N in frozen N_2O showed that a small deviation from the equiprobability of these molecular orientations leads to a drastic effect on the spontaneous Raman scattering line shapes [93].

The consequences of head-to-tail disorder in crystalline N_2O have been studied by means of molecular dynamics simulations of the IR and Raman spectra of the lattice vibrations [94]. Single particle and collective mode properties were analyzed, also in relation to the cause of line broadening associated with the head-to-tail disorder. The study was extended to study the effect of dipolar disorder on the internal symmetric stretching mode ν_1 in the IR and Raman spectra of frozen N_2O [95].

Rietveld refinements of angle-resolved powder XRD data indicated that the crystal structure of CO_2 and N_2O phase IV adopts a post-stishovite-type $\alpha\text{-PbO}_2$ structure ($Pbcn$, $Z=4$); $\text{N}_2\text{O-IV}$ ($a=4.236[1]$ Å, $b=5.982(1)$ Å, and $c=4.223(1)$ Å) [96]. In these phases, both CO_2 and N_2O molecules are bent (133° for $\angle\text{N—N—O}$), with relatively long intramolecular bond distances and relatively short intermolecular bond distances. However, in contradistinction to carbon atoms in CO_2 , nitrogen atoms at the center of N_2O maintain the fcc positions of phases I or III.

The lattice dynamics of molecular crystal N_2O can be treated throughout the Brillouin zone within the framework of classical harmonic approximation. Density of states and heat capacity at low temperatures could be obtained by applying a potential computation method [97]. The results were in good agreement with available experimental data. The lattice frequencies of the isomorphous crystallized CO_2 calculated by using the same potential method agreed well with neutron scattering data.

3.4.3 Dipole Moment of Nitrous Oxide

The opposite charge distribution in the resonance forms A and B

accounts for the relatively low dipole moment of the molecule (0.161 D).

The N_2O dipole moment is very sensitive to two bond lengths and to the electron correlation. This can be measured in adducts of N_2O with the strong acid hydrogen fluoride HF [98]. The $\text{N}_2\text{O}\cdots\text{HF}$ adduct has two minima on the energy hypersurface corresponding to bent $\text{NNO}\cdots\text{HF}$ and linear $\text{FH}\cdots\text{NNO}$ structures. The activation energy between the two minima was estimated to be 497 cm^{-1} . The stability and structures of $(\text{N}_2\text{O})_2$ dimers, $\text{N}_2\text{O}\cdots\text{BH}_3$, $\text{N}_2\text{O}\cdots\text{NH}_3$ adducts were also examined. One would assume that two NNO molecules might associate in a “head-to-tail” orientation and form a dimer $(\text{N}_2\text{O})_2$, but measurements have shown that of the two structures, only the one having the oxygen atoms close to one another is experimentally observed.

The proton affinity of N_2O is very low, but protonated N_2OH^+ has been observed in the gas phase. The infrared spectra indicate that the proton would preferentially dwell at the oxygen atom and not at any of the two nitrogen atoms [99].

3.4.4 Other Isomers or Oligomers of Nitrous Oxide

Monomeric nitrous oxide may possibly also exist in a short-lived, cyclic form of an oxdiazirane:

Further studies of this structural isomer would be valuable for its potential evaluation as a rocket propellant, if it can be shown that it is more energetic than linear NNO and if it can be stabilized. It might also be possible to decompose this compound spontaneously on a catalyst at room temperature and use it as a monopropellant like hydrazine so that one does not have to preheat the catalyst. The structure of the cyclic molecule is similar to that of ethylene oxide, which can also be used as a monopropellant.

The reaction of OF_2 with NaN_3 or CsN_3 gave dinitrogen and nitrous oxide in a molar ratio of roughly 1:2, but not the expected oxygen azide:

This may proceed by intermediate formation of $\text{O}(\text{N}_3)_2$, which decomposes into N_2O and two equivalents of N_2 . The structure, energy, and vibrational frequencies of the not previously described $\text{O}(\text{N}_3)_2$ were computed by *ab initio* methods [100]. The formation of linear N_2O as the product of the reaction of OF_2 with CsN_3 can best be explained by the intermediate formation of $\text{O}(\text{N}_3)_2$, which then decomposes in a unimolecular reaction to yield N_2 and cyclic N_2O (C_{2v}), the latter of which then rearranges to form the more stable linear isomer of N_2O ($C_{\infty v}$). If cyclic $\text{NON}(C_{2v})$ existed, one would expect it to have the following bond lengths and bond angles: $\text{N}-\text{N}$ 1.214 Å, $\text{N}-\text{O}$ 1.511 Å, $\angle\text{NON}$ 47.4°, $\angle\text{NNO}$ 66.4°.

Clusters of two or more molecules of N_2O survive long enough to be identified if a jet of the gas is expanded into vacuum to form a molecular beam. Supersonic expansions of nitrous oxide seeded in argon were studied by single pass FTIR absorption at right angles with the jet axis [101]. In very dilute mixtures, 0.2% N_2O , dimer bands at 1282.4 and 2228.0 cm^{-1} were observed. Cluster bands (due to clusters of undetermined size) were readily observed in 20–100% N_2O mixtures at 1165.1, 1295.2, 2245.6, 2467.4, 2578.3, 2811.7, and 3505.8 cm^{-1} . All bands were shifted from the corresponding monomer bands more than in the crystal and in the same direction. Changing the dilution from 10 to 20% shifted all cluster bands 1–2 cm^{-1} towards low frequencies but still far away from the crystal frequencies. This was interpreted as being due to cluster melting.

In addition to finding dimers in expanding flows, N_2O dimers can also be found by their IR spectra in cryogenic matrices. The IR spectra of the dimers of carbon dioxide and nitrous oxide have been recorded in nitrogen and argon matrices at about 17 K [102]. The spectra have been interpreted in terms of the presence of weak van der Waals molecular complexes, stabilized in one instance by quadrupole-quadrupole and in the other by dipole-dipole interactions. The structures of the dimers deduced on the basis of the spectra have been compared with those predicted by *ab initio* studies and with those determined in the gas phase and in some earlier matrix isolation studies.

High-resolution IR spectroscopy has been used in conjunction with *ab initio* calculations to identify the structure of a nitrous oxide tetramer [103]. It was possible to observe a non-planar structure in which all four molecules were approximately parallel. The high symmetry of this system made the spectral assignment straightforward. In fact, the *ab initio* calculations and experiment indicated that this system is very nearly a spherical top with rotational constants $A'' = B'' = 0.0248 \text{ cm}^{-1}$ and $A' = B' = 0.02495 \text{ cm}^{-1}$. The C rotational constant could only be roughly estimated to be 0.02 cm^{-1} from the relative intensities of the Q and P, R branches observed in the C -type band.

Clusters of N_2O in a molecular beam can be disassembled selectively by tuning the energy of an electron beam until cluster splitting is observed. The interaction of electrons of carefully controlled energy with a molecular beam of N_2O molecules and clusters has been studied in a pulsed crossed-beam arrangement over the energy range from threshold to 200 eV [104]. A variety of time-resolved techniques was applied to isolate and study many of the dissociative excitation channels that occurred. The degree of clustering in the target beam does not have much effect on the cluster dissociation energy.

Large N_2O clusters containing up to 177 molecules were simulated using a semiempirical computational chemistry method called AM1 [105]. Simulated spectra of different cluster sizes showed excellent agreement with experimental spectra. The vibrational band shape of the strong N—N stretching vibration was more strongly influenced by shape and size than that of the N—O stretching vibration. Stabilization energies and spectral band shapes confirmed a crystal-like structure of N_2O clusters generated in supersonic jet expansions. The AM1 results were compared to experimental and high-level *ab initio* methods, and it was shown that AM1 reproduced experimental results (structure and vibrational frequencies) and MP2 dissociation energies of small N_2O clusters far better than any other quantum mechanical method.

In search of more energetic or easier to store derivatives of nitrous oxide, calculations for hypothetical nitrous oxide oligomers were performed, examining the possibility of the existence of a cyclic trimer (N_2O)₃. The predicted heats of its formation calculated by different methods indicated that there is a small energy barrier before the trimer converts back to the monomer N_2O . Two isomeric structures are possible for the trimer, one is a benzene analog, resonance-stabilized ring structure, and the other is a 1,4-diox-2,3,5,6-tetrazane six-membered ring:

High pressure may facilitate a range of stability for these unusual compounds. A trimer of nitrous oxide has been observed in a molecular beam by IR spectroscopy.

A laser has been used in conjunction with a molecular-beam apparatus to study the infrared vibrational predissociation spectra of nitrous oxide clusters near the $\nu_1 + \nu_3$ vibrational combination band of the monomer [106]. These spectra were recorded as a function of source pressure in order to measure their dependence on cluster size. A frequency shift, corresponding to a gradual transition from the vapor to the solid state, was observed as the cluster size increased. Cluster-size distributions

were estimated using both quadrupole and ion time-of-flight mass spectrometry. The latter technique showed cluster sizes well in excess of $(\text{N}_2\text{O})_{100}$.

The structure of the nitrous oxide dimer was determined from sub-Doppler resolution infrared spectroscopy [107]. An opto-thermal detection method has been used to obtain rotationally resolved infrared spectra for both $(^{14}\text{N}^{14}\text{N}^{16}\text{O})_2$ and $(^{15}\text{N}^{14}\text{N}^{16}\text{O})_2$ dimers. The vibrational band observed in each case correlated well with the $\nu_1 + \nu_3$ band of the N_2O monomer. Isotopic substitution showed that of the two structures, only the one having the oxygen atoms close to one another is experimentally observed. The structural constants were determined to be $r_{\text{N}-\text{N}} = 3.493(4) \text{ \AA}$ and $\angle \text{NNO} = 59.2(5)^\circ$.

3.4.5 Computational Chemistry of Nitrous Oxide Molecules

Computational chemistry has been applied to single N_2O molecules, to N_2O clusters, and to N_2O adducts with other compounds. The objective was to find molecules that are more energetic than N_2O itself.

Multi-local minima on the potential energy surface of the electronic ground state of the N_2O molecule were predicted by various *ab initio* methods [108]. The calculations confirmed that the global minimum of the molecule possesses an N—N—O linear structure with $C_{\infty v}$ symmetry, as experiment and other theoretical calculations have already indicated. Calculations also predicted other local minima on the energy surface: a less stable cyclic isomer with a C_{2v} symmetry and a least stable linear N—O—N isomer with a $D_{\infty h}$ symmetry. The electronic structures of the local minima indicated that the energy of the system increased if the N—N bond of the molecule becomes weak (the cyclic C_{2v} case) or breaks (the linear $D_{\infty h}$ case). The electronic structure and stabilities of the local minima of the N_2O molecule potential energy surface gave a qualitative valence bond representation for the $C_{\infty v} \rightarrow C_{2v} \rightarrow D_{\infty h}$ isomerization energy differentials.

STO-6G calculations indicated that a valence-bond structure for N_2O generates a lower energy than does resonance between two valence-bond structures with π electron configurations [109]. In each of these three structures, the central nitrogen atom is apparently pentavalent. For N_2O , the bond orders that are implied by the structure

were shown to be in qualitative accord with the observed bond lengths. Estimates of the lengths of “normal” N=N and N=O double and triple bonds are 1.24 Å ($\text{H}_3\text{C}-\text{N}=\text{N}-\text{CH}_3$), 1.10 Å (N_2), 1.21 Å ($\text{H}_3\text{CN}=\text{O}$), and 1.06 Å (NO^+). Therefore, the N—N and N—O bond lengths of 1.13 and 1.19 Å for N_2O are only slightly longer than the N≡N triple bond of N_2 and similar to an N=O double bond.

The results of STO-6G valence bond calculations with Lewis-type valence bond structures were reported for the $S = 0$ spin ground states of the linear NNO ($C_{\infty v}$) and NON($D_{\infty h}$) isomers of N_2O [110]. It was shown that the singlet diradical character of the NON isomer is substantially larger than for the NNO isomer. Results of B3LYP/6-

31G(d) density functional calculations were also reported for the $C_{\infty v}$ and $D_{\infty h}$ ground states, the single determinant approximations to the lowest-energy $S = 1$ spin excited states of these two isomers, and for the triangular C_{2v} isomer. The calculated bond lengths were in accord with qualitative valence bond considerations. Molecular orbital calculations for the $O(N_3)_2$ decomposition showed that it can lead to a cyclic isomer of N_2O as a short-lived intermediate.

Lennard-Jones parameters of size and energy of force fields for nitrous oxide and dioxygen were determined by fitting the theoretical results to measured single component vapor/liquid equilibrium data [61]. The force fields accurately described the vapor/liquid two-phase coexistence curves of nitrous oxide, as shown in the vapor pressure plot (Figure 25) and the heat of evaporation plot (Figure 26). In addition to single component phase coexistence simulations, the phase equilibria of binary mixtures including N_2O/O_2 and N_2O/N_2 were simulated without further adjustment of the model parameters and found to be in good agreement with experimental data.

Open symbols represent experimental data and filled symbols the simulation results calculated by [61].

A global potential-energy surface was calculated for the electronic ground state of N_2O [111]. The new form was shown to accurately mimic the *ab initio* points calculated at the multi-reference configuration interaction level. The topographical features of this potential-energy surface were examined in detail and compared with those of other potential functions available in the literature and good agreement with experimental data was observed.

First-principles molecular-dynamics simulations based on density-functional theory were used to study the electronic and optical properties of fluid nitrous oxide under extreme pressure and temperature conditions [112]. Systematic descriptions of the pair-correlation function, the atomic structure, and the charge density distribution were used to investigate the dissociation of fluid nitrous oxide. It was found that the non-metal-metal transition for fluid nitrous oxide can be directly associated to the dissociation and has a significant influence on the optical properties of the fluid.

3.5 Optical Properties of Nitrous Oxide

3.5.1 Ultraviolet Spectra of Nitrous Oxide

Knowledge about the ultraviolet spectrum of nitrous oxide would be useful for laser ignition of nitrous oxide reactions. It is also fundamental in trying to understand the rate of N_2O destruction by photolysis in the stratosphere and calculating the mean lifetime of N_2O once it is released into the atmosphere as the result of anthropogenic industrial and biological processes.

A reinvestigation of the UV absorption spectrum of nitrous oxide agreed with previous results in the range 210 to 235 nm, but contrary to the previous results it indicated

a vanishingly small cross section above 260 nm [113]. The absence of the relatively long wavelength absorption implied a negligible rate of photolysis of nitrous oxide in the troposphere. These results plus the previously estimated atmospheric mean residence times of N_2O indicate that there may be a large, unknown tropospheric sink for nitrous oxide.

The UV absorption spectra of nitrous oxide and its ^{15}N isotope-substituted isomers were measured from 172 to 330 nm [114]. The long wavelength absorption above 265 nm was shown to be almost entirely due to Rayleigh scattering. This reduces the calculated rate of nitrous oxide photolysis in the troposphere to a very small value. Spectra over the wavelength range 172 to 190 nm demonstrated that the diffuse bands are a separate pronounced absorption of nitrous oxide, which is strongly affected by temperature. This banding is the result of transitions to discrete vibronic levels in an upper electronic state.

The UV absorption spectra of nitrous oxide and its ^{15}N isotopologues over the wavelength range 197 to 172 nm and between 150 and 500 K showed a weak continuous absorption and a pattern of diffuse banding that became more pronounced at higher temperatures [115, 116]. Spectra were measured at room temperature, 151, 333, and 485 K. The temperature dependence of the absorption spectrum results from the activation of the ν_2'' bending mode. Deconvolution of the data showed that absorption by molecules in the (010) vibrational mode results in a spectrum of vibrational bands superimposed on a continuum. A weaker and nearly continuous spectrum results from the ultraviolet absorption by molecules in the (000) vibrational mode. No rotational structure could be observed. The spectra of N_2O with natural isotope distribution were compared to those of $^{14}\text{N}^{15}\text{NO}$, $^{15}\text{N}^{14}\text{NO}$, and $^{15}\text{N}^{15}\text{NO}$. Measurement of the ν_2'' isotope shift was used to identify the quantum number of the upper state vibrational levels. Absorption cross section spectra of nitrous oxide for a wavelength range from 173 to 197 nm are shown in Figure 27.

Figure 27: Absorption cross sections for $^{14}\text{N}^{14}\text{N}^{16}\text{O}$ at temperatures listed in the legend: (from bottom to top) 148, 213, 301, 372, 442, and 503 K. (From [115].)

The isotopically substituted nitrous oxide isotopologues $^{14}\text{N}^{14}\text{NO}$, $^{15}\text{N}^{14}\text{NO}$, $^{14}\text{N}^{15}\text{NO}$, and $^{15}\text{N}^{15}\text{NO}$ were investigated by UV absorption spectroscopy, and high-precision cross sections were obtained for the wavelength range 181 to 218 nm at 233 and 283 K [117]. These data were then used to calculate photolytic isotopic fractionation constants as a function of wavelength. The fractionation constants were used in a three-dimensional chemical transport model in order to simulate the actual fractionation of N_2O in the stratosphere, and the results were found to be in good agreement with field studies.

3.5.2 Infrared Spectra of Nitrous Oxide

The nitrous oxide molecule is unsymmetrical and, therefore, should have a dipole moment and an infrared absorption spectrum. The knowledge of IR spectra of N_2O is important for calculating its thermodynamic properties, for detection of N_2O leaks in the atmosphere near rocket test sites using N_2O , and for measuring the greenhouse effect contributions by N_2O in the upper atmosphere. Nitrous oxide, being a polar molecule, may associate to oligomers in the vapor phase at low pressures, typically studied in molecular jets. Infrared spectra of N_2O under these conditions help to determine how many N_2O molecules may have agglomerated in these clusters [103]. It is mostly due to the participation of nitrous oxide in atmospheric chemistry and energy balance that the infrared spectra of this compound have been so thoroughly investigated during the past 20 years, including the use of isotope-labeled molecules to identify the molecular vibrations and rotations that cause certain IR absorption bands. The detection and analysis of nitrous oxide as a rocket propellant benefits from the spectroscopy work done by the atmospheric chemistry researchers. IR spectroscopy would allow us to measure undecomposed N_2O in the rocket plume from a hybrid or monopropellant rocket engine.

On closer examination with a high-resolution spectrometer, all the bands in Figure 27 are revealed to consist of a multitude of very narrow absorption lines that can be assigned to specific vibration and rotation states of the molecule.

A typical wide-range, low-resolution IR spectrum of nitrous oxide gas is shown in Figure 28. The spectrum of gaseous nitrous oxide has been measured with a high-resolution grating spectrometer in the region from 2395 to 3510 cm^{-1} [118]. Long absorbing paths were used in a heated cell, so that it was possible to observe many of the weaker bands, including those with lower vibrational levels ν_2 , $2\nu_2^0$, $2\nu_2^2$, and ν_1 . From the line frequencies, accurate values of the rotational constants have been obtained, including the I -type doubling and variations with ν and I of the centrifugal stretching constant.

In one of the first high-resolution spectra recorded using an antique echelle spectrograph, almost 400 lines from five N_2O absorption bands arising from the ground state of the molecule have been measured [119]. The molecular constants of the above bands were then determined by making use of combination relationships applying

Figure 28: Infrared spectrum of gaseous nitrous oxide. (Reproduced and modified with permission from Coblenz Society, Inc., Evaluated Infrared Reference Spectra in NIST Chemistry WebBook, NIST Standard Reference Database Number 69, Eds. P.J. Linstrom and W.G. Mallard, National Institute of Standards and Technology, <https://doi.org/10.18434/T4D303>, retrieved June 7, 2021)

least-squares methods to the data. The line frequencies were then calculated to four decimal places and presented in tables that contained over 600 line frequencies.

Measurements of the vibration-rotation bands of nitrous oxide occurring at 4.5μ yielded improved values for some of the rotational constants of this molecule [120].

Extending the spectroscopy from N_2O with natural isotope distribution to isotope-labeled N_2O , the IR spectra of $^{15}\text{N}^{14}\text{N}^{16}\text{O}$ and $^{15}\text{N}_2^{16}\text{O}$ were measured with a high-resolution grating spectrometer in the region between 2100 and 4450 cm^{-1} and the spectrum of N_2O with natural isotope distribution $^{14}\text{N}_2^{16}\text{O}$ was remeasured for comparison in order to obtain accurate values of the isotopic shifts [121]. Twelve vibration-rotation bands of each isotopic species were analyzed, and from the rotational constants obtained it was possible to determine improved equilibrium internuclear distances $r_{\text{N-N}} = 1.1282\text{ \AA}$, $r_{\text{N-O}} = 1.1842\text{ \AA}$ for the nitrous oxide molecule.

High-resolution IR spectra of N_2O in the range from 1830 to 2270 cm^{-1} were obtained with optical path lengths of 1.2, 4, and 24 m and pressures ranging from 1 to 200 mm Hg [122]. The 1.2-m cell could either be cooled to 220 K or warmed to 400 K. At that high resolution, the absorption bands in Figure 28 can be resolved into individual rotation bands. The two high-resolution spectra in Figures 29 and 30 remind one of the proverbial “picket fence” spectrum. Once the moments of inertia of the molecule were known, vibration frequencies could be calculated, and the calculated results agreed quite well with the measured frequencies. By comparing the spectra of $^{14}\text{N}^{14}\text{N}^{16}\text{O}$, $^{14}\text{N}^{15}\text{N}^{16}\text{O}$, $^{15}\text{N}^{14}\text{N}^{16}\text{O}$, and $^{14}\text{N}^{14}\text{N}^{18}\text{O}$, individual bands in the spectra could be assigned to specific modes of vibration and their harmonics.

The zero-order frequencies, and the anharmonic and vibration-rotation coupling constants up to fourth order have been calculated for $^{14}\text{N}_2^{16}\text{O}$ from a careful analysis of all available experimental data on the vibration-rotation energy levels of the molecule [123, 124]. It was found necessary to include the fourth-order constants in the energy expression in order to reproduce the recent accurate measurements to within their experimental uncertainties. Anharmonic interactions influence the energy levels. To

Most of the spectroscopy work discussed here deals with absorption spectra of nitrous oxide. However, when the molecule is excited by other means other than Brownian motion and thermal energy, e.g., in a glow discharge or a DC arc, it will also emit infrared vibrational luminescence radiation in specific frequency ranges. High-resolution measurements have been performed on 19 emission and absorption bands of the nitrous oxide molecule at 4.7 and 2.9 μm , and from these, accurate values of the vibrational and rotational constants of 23 vibration levels could be obtained [133].

Several bands of nitrous oxide occurring in the region of about 5.3 μm were measured by using a high-resolution vacuum infrared spectrograph, and the line frequencies were used to calculate the molecular constants [134].

A high-precision wavenumber calibration has been achieved for the spectrum of N_2O at 4.5 μm [135]. The values of the wavenumbers were reported for the $(00^0_1-00^0_0)$ and for the $(01^1_1-01^1_0)$ transitions in the ν_3 and the $(\nu_2 + \nu_3 - \nu_2)$ bands, giving a new set of molecular constants for the upper and lower levels of these two transitions. In particular, the value of the H constant for the ground state $(-2.02 \pm 0.4) \times 10^{-13} \text{ cm}^{-1}$ reported was significantly different from previous results.

The high-resolution infrared spectrum of N_2O in the region of ν_2 was recorded with an FTIR spectrometer at a resolution of $\sim 0.005 \text{ cm}^{-1}$ [136]. In addition to ν_2 , “hot” bands associated with this band and the bending fundamental ν_2 of $^{15}\text{N}^{14}\text{N}^{16}\text{O}$ and $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ were analyzed.

An N_2O spectroscopic database suitable for high temperature and medium resolution applications has been created in the 4.5 μm region [137]. Intensities of $^{14}\text{N}_2^{16}\text{O}$ hot bands were extrapolated from the ν_3 band intensity, and energies of vibrational levels were computed. Pure N_2O spectra were recorded with an FTIR spectrometer at temperatures up to 900 K and with 1 cm^{-1} resolution. At that temperature, N_2O is already in a predissociation stage. A good agreement between these spectra and line-by-line calculations was obtained.

The absorption spectra of a $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ -enriched sample of nitrous oxide were recorded at Doppler-limited resolution with an FTIR spectrometer in the spectral range 3500–9000 cm^{-1} [138]. More than 12000 transitions of $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ were observed and ro-vibrationally assigned on the basis of a global effective Hamiltonian model. The band-by-band analysis led to the determination of the ro-vibrational parameters of a total of 107 bands. Among the 107 bands, 80 were newly observed, and for 27 others the rotational analysis was significantly extended and improved. The effective Hamiltonian parameters were determined from global fitting to the observed line positions. As a result, a set of 117 obtained effective Hamiltonian parameters reproduced 16134 observed line positions of 148 bands with an accuracy of $\pm 0.0014 \text{ cm}^{-1}$.

Vibrational-rotational line positions of the $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ and $^{15}\text{N}^{14}\text{N}^{16}\text{O}$ isotopologues of nitrous oxide were fitted using a Hamiltonian approach describing all rovibrational energy levels in the ground electronic state and containing in explicit form all resonance interaction terms due to the approximate relations between

harmonic frequencies [139]. For $^{14}\text{N}^{15}\text{N}^{16}\text{O}$, 124 effective Hamiltonian parameters were fitted to near 28000 observed line positions covering the 0.8–8860 cm^{-1} spectral range. For $^{15}\text{N}^{14}\text{N}^{16}\text{O}$, 121 effective Hamiltonian parameters were fitted to more than 31000 observed line positions covering the same spectral interval. In both cases, the models described all available line positions with precision compatible to the measurement uncertainties.

Using FTIR spectra of the nitrous oxide isotopologue $^{15}\text{N}_2^{16}\text{O}$, the line positions and intensities have been measured for 511 lines of 8 cold bands and 1 hot band lying between 5800 and 7600 cm^{-1} [140]. A multi-spectrum fitting procedure has been used to retrieve line parameters from five experimental spectra recorded at different pressures. The line positions measured and those collected from the literature allowed the global fitting of the effective Hamiltonian parameters for this isotopologue, giving very accurate inertia moments and bond distances.

Cavity ring-down spectroscopy is a form of laser absorption spectroscopy. In cavity ring-down spectroscopy, a laser pulse is trapped in a highly reflective detection cavity [141, 142]. The $6\nu_3$ and $\nu_2 + 6\nu_3 - \nu_2$ bands of ^{15}N -substituted nitrous oxide isotopologues have been recorded by a continuous-wave cavity ring-down spectrometer operated near 0.8 μm [143]. In total, 213, 86, and 191 transitions were observed for the $^{14}\text{N}^{15}\text{N}^{16}\text{O}$, $^{15}\text{N}^{14}\text{N}^{16}\text{O}$, and $^{15}\text{N}_2^{16}\text{O}$ isotopologues, respectively. The ro-vibrational spectroscopic parameters of the upper states were determined from least square fitting of the transitions. The absolute line intensities of the $6\nu_3$ cold bands were retrieved by a multi-line fitting procedure from the spectra for the majority of the unblended lines.

The absorption spectrum of nitrous oxide has been recorded by Intracavity Laser Absorption Spectroscopy between 12760 and 12900 cm^{-1} [144]. The rotational analysis led to an improved determination of rovibrational parameters of the $6\nu_3$ and $6\nu_3 + \nu_2 - \nu_2$ bands of $^{14}\text{N}_2^{16}\text{O}$. The high J rotational levels of the (00^0_6) and (01^1_6) upper states were found perturbed by an anharmonic interaction. Line intensity values of the $6\nu_3$ band were tabulated, and the main effective dipole moment parameter of this molecule was then determined.

3.5.2.1 Infrared Spectra of Solid and Matrix-Isolated Nitrous Oxide

There are hundreds of publications on IR spectra for gaseous N_2O , hardly any for liquid N_2O , and only a few for solid N_2O . Chilling N_2O until it solidifies would also freeze the rotational structure and broaden the other bands due to interaction of closely packed molecules.

The infrared spectrum of solid nitrous oxide was measured at 80 K [145]. In contradistinction to CO_2 , no evidence for splitting due to intermolecular coupling or for reflection peaks in the spectrum was observed. Spectral features assigned to torsional lattice motions (with fundamentals at 80 and 91 cm^{-1}) and to translational lattice motions (as broadening of ν_3) could be seen.

Nitrous oxide was isolated in pressed alkali halide matrices [146]. Its three infrared active fundamentals appeared at room temperature as single peaks and without

the gas phase rotational structures. Cooling of the host matrix caused these bands to sharpen and to shift to higher frequencies. At any given temperature, however, the peak frequencies were essentially independent of the host matrix. The temperature dependence of the most intense ν_3 fundamental was examined in detail, and the results indicated that there were two dominant trapping sites for N_2O in pressed KCl, KBr, or KI matrices.

The IR spectrum of crystalline nitrous oxide showed longitudinal-transverse mode splitting of the three fundamentals and factor group splitting of ν_2 [147]. A large number of internal isotopic and combination bands have been assigned. In the region of combination bands extended two-phonon absorption bands have been observed, which were particularly prominent in the region of $\nu_1 + \nu_3$ and $\nu_2 + \nu_3$. The energy of one- and two-phonon states has been calculated using a resonant dipole-dipole interaction potential. The results of calculation agreed well with experiments. The intensity and profile of the two-phonon bands was calculated using a mechanism of induced dipoles. It was shown that two-phonon bands arise by direct excitation via non-linear terms in the dipole operator.

In studying the temperature dependence of the far infrared active lattice modes of solid nitrous oxide, spectra of solid N_2O were precisely measured in temperature range from 1.8 to 130 K [148]. Remarkable temperature dependence of the absorption bandwidths was obtained and explained by means of the perturbation theory of the anharmonic crystal. The results suggested ways in which the lattice vibration energy is dissipated. No dipole ordering was found by the spectroscopic studies.

The vibrational spectrum of solid N_2O diluted in a frozen nitrogen matrix was compared to the spectrum of N_2O produced after the photolysis of ozone diluted in solid nitrogen [149]. The photolysis of ozone produced atomic oxygen. The small shift observed between the two spectra was found to be due to the formation of a 1 : 1 complex between nitrous oxide and molecular oxygen. Upon increasing the temperature, the complex formed after the photolysis of ozone in nitrogen reacted with an oxygen atom leading to O_3 and N_2O .

Isotopically labeled nitrous oxide has been produced in solid nitrogen matrices using mixtures of nitrogen and water containing ^{14}N , ^{15}N , ^{16}O , ^{17}O , and ^{18}O [150]. All 12 possible N_2O isotopologues and isotopomers were obtained, and their fundamental, overtone, and combination frequencies were assigned by the joint use of infrared spectroscopy and quantum chemical calculations. The nitrogen matrix has some influence upon frequency and anharmonicity of the vibrations.

The physical properties of nitrous oxide are very similar to those of carbon dioxide. Just like there is carbon dioxide snowing at the polar caps of Mars, there might be other celestial bodies where it is snowing nitrous oxide instead. This is why the reflection spectra of solid N_2O in all wavelengths are of astrophysical interest.

Figure 31 is a composite of three spectra of solid nitrous oxide at 16 K taken at three different wavelength ranges. Note that the optical depth ordinate scale is different for each of these three segments.

Figure 31: Infrared spectra of solid nitrous oxide at 16 K. (Reprinted and modified from [38], with permission from © 2009 Elsevier; permission conveyed through RightsLink.)

The peak positions and the band assignments from the spectra above are listed in Table 20. Similar spectra were obtained for $\text{NO}_2/\text{N}_2\text{O}_4$ equilibrium mixtures flash-frozen at 16 K.

Table 20: Peak positions of the IR bands of solid N_2O deposited at 16 K and their assignment.

Wavenumber, cm^{-1}	Vibration mode
1166	$2\nu_2$
1295	ν_1
2239	ν_3
2469	$\nu_1 + 2\nu_2$
2581	$2\nu_1$
2814	$\nu_2 + \nu_3$
3380	$2\nu_2 + \nu_3$
3509	$\nu_1 + \nu_3$

Data source: [38]

Table 21 gives a comparison of absorption coefficients of nitrous oxide as a gas at 300 K and dissolved in liquid oxygen (LOX) at 90 K. The frequencies, half-widths, and intensities of bands in the infrared spectra of linear molecules (N_2O) dissolved in LOX were measured at 90 K and compared with the results obtained from the spectra in the gas phase [151]. Solutions whose concentrations were known to be lower than saturated were prepared by liquefaction in a cryostat of standard gas mixtures of the gas with oxygen. On condensation the partial pressure of the gas was lower than the vapor pressure over solid N_2O to avoid N_2O precipitation. The standard mixtures were chosen such that in most cases, the vibrational frequencies underwent a shift to lower

frequencies on going from the gas phase to the LOX solution. Once the absorption coefficient of N_2O at its strongest ν_1 absorption band was known, this method could be used to determine N_2O concentrations in LOX solutions used as rocket propellant.

Table 21: Absorption coefficients of nitrous oxide as a gas and dissolved in liquid oxygen.

Band assignment	Gas at 300K	In liquid oxygen at 90K	Band half-width $\Delta\nu_{1/2}$
	$A \times 10^8, \text{cm}^2 \text{mol}^{-1} \text{s}^{-1}$	$A \times 10^8, \text{cm}^2 \text{mol}^{-1} \text{s}^{-1}$	
$\nu_1 \Sigma$	29.9	29.5 ± 1	2.7
$\nu_2 \Pi$	4.6–2.3	3.3	1.2
$\nu_3 \Sigma$	157 ± 10	164 ± 10	2.7
$2\nu_1 \Sigma$	4.9 ± 0.5	5.1	3.2
$2\nu_2 \Sigma$	1.3–0.9	1.0	2.6
$2\nu_3 \Sigma$	0.18	0.16	3.6

3.5.3 Raman Spectra of Nitrous Oxide

Raman scattering in the lattice region (25 to 200 cm^{-1}) of frozen N_2O at 90 , 120 , and 170 K has been investigated using He-Ne gas laser excitation [153]. The structure of crystals in polycrystalline N_2O lacks a symmetry center, and the site group is C_3 and the space group is T^d ($P2_13$). The greater band widths in the N_2O spectrum (compared to CO_2) may be attributed to crystalline disorder (Table 22). The origin of the shoulder observed near 111 cm^{-1} is uncertain. It may correspond to the band observed at 113 cm^{-1} in the far-infrared spectrum of N_2O at 65 K .

Table 22: Temperature dependence of Raman lattice frequencies of N_2O .

Temperature, K	Wavenumber, cm^{-1} (half-height width in parentheses)		
90	68 (8)	80 (5)	122 (8)
120	64	76	119
170	61 (12)	71 (shoulder)	110 (13)

Data source: [153]

A comparison of Raman stretching mode ν_1 line intensities expected for a random distribution of molecular orientations $\text{N}-\text{N}-\text{O}$ and $\text{O}-\text{N}-\text{N}$ in frozen N_2O showed that a small deviation from the equiprobability of these molecular orientations leads

to a drastic effect on the spontaneous Raman scattering line shapes [93]. It was concluded that N_2O crystals grown from the gas phase were not totally disordered.

The isoelectronic molecules CO_2 and N_2O form crystals of cubic symmetry, with space groups T_h^6 and T^4 , respectively. Laser-excited Raman spectra of polycrystalline solid samples of CO_2 and N_2O (Figure 32) excited by the $5145\text{ \AA}$ line of an argon laser operating at about 433 mW power were measured at 79 and 18 K, and lattice and molecular modes were assigned according to predictions from the known crystal structures, and the observed lattice frequencies were compared with calculated values [154].

Figure 32: Raman spectra of polycrystalline nitrous oxide at 18 K. (Reprinted and modified from [154] with permission from © 1971 Elsevier, permission conveyed through Copyright Clearance Center, Inc.)

The absence of a center of symmetry in N_2O results in a more detailed Raman spectrum. In the lattice region, besides the three librational modes, four translations are Raman active. However, apart from increases in line widths, the observed spectrum is very similar to that of CO_2 , indicating that the translations are very weakly Raman active, possibly as a result of the residual disorder. All three intramolecular modes of N_2O are Raman active, with two components predicted for each of the stretching vibrations and three for the bending mode.

Raman studies as a function of pressure ($P < 40\text{ GPa}$) and temperature (20–300 K) have been made of the external and internal modes of solid N_2O , and the pressure dependence of external and internal modes was determined [155]. The occurrence of orientational disorder manifested itself in the line shape of the lattice and intramolecular modes. A new high-pressure phase $\text{N}_2\text{O-II}$ was found above 5.5 GPa. The temperature shift of the external mode wave numbers was found to decrease drastically with increasing pressure.

Based on *in situ* high-pressure, high-temperature Raman spectroscopy, two new solid phases were discovered in the phase diagram of nitrous oxide [156]. The two

new solid phases were stabilized by heating the room temperature orthorhombic nitrous oxide at pressures between 12–35 GPa and temperatures above 500 K. Both new phases could be quenched metastably to room temperature, where they remained stable over a wide range of pressures between 5–60 GPa. The appearance and properties of the new phases were similar to those of the high pressure-high-temperature phases of carbon dioxide. However, the similarity between the two isoelectronic molecules ends at temperatures above 1000 K, where nitrous oxide disproportionates to form an ionic solid (nitrosonium nitrate), while carbon dioxide forms a covalent solid.

When β -nitrous oxide ($Cmca$ N_2O) was laser-heated to between 2000 and 3400 K at high pressures (10–55 GPa), it disproportionated into an ionic form of dimeric nitrous dioxide ($NO^+NO_3^-$) and nitrogen [157]. Raman spectra of the quenched products suggested that the ionic phase was stable to 55 GPa at ambient temperature but, upon subsequent heating at pressures below 30 GPa, further dissociated into nitrogen, oxygen, and other nitrogen-oxygen compounds. XRD patterns of the ionic phase indicated that it has an orthorhombic structure ($Z = 4$, $\rho_o = 2.69 \text{ g/cm}^3$), similar to the aragonite phase of calcium carbonate. The results suggested that the primary driver for ionization is densification at high pressures, whereas dissociation between 10 and 30 GPa resulted from the combined effects of densification and entropy increases.

3.5.4 Microwave Spectra of Nitrous Oxide

Rotational lines of N_2O have been measured with high precision in the region of 1 to 3 mm wavelength (100 to 300 GHz) for nine $J \rightarrow J + 1$ transitions between $3 \rightarrow 4$ and $11 \rightarrow 12$. These microwave measurements have given very precise values for the ground-state rotational constant, $B_0 = 12561.63 \text{ MHz}$, $D_J = 5.359 \text{ kHz}$, and the I-doubling constant, $q = 23.73_6$, of the $^{14}N^{14}N^{16}O$ molecule [158].

Rotational transitions observed between 125 and 302 GHz ($J = 4 \rightarrow 5$ to $J = 11 \rightarrow 12$) have provided improved rotational and centrifugal distortion constants for the (00^0_0) , (01^{1c}_0) , (01^{1d}_0) , (02^0_0) , (02^{2d}_0) , (02^{2c}_0) , and (10^0_0) vibrational levels of $^{14}N_2^{16}O$ [159]. The splitting of the (02^2_0) state due to I -type resonance was well resolved, and a correlation between B_v and D_v was studied; B_0 and D_0 were $12561.6338 \pm 0.0006 \text{ MHz}$, and $5.282 \pm 0.004 \text{ kHz}$, respectively.

The submillimeter wave spectrum of N_2O within the 375–565 GHz frequency range included 161 lines belonging to 22 spectroscopically different states of the molecule (specifically, the ground and some excited vibrational states of the five most abundant isotopic species of the molecule in natural abundance) [160]. Rotational and two centrifugal stretching constants could be determined for each spectroscopic species. The total number of the rotational and rovibrational constants exceeded 40.

High-precision microwave absorption measurements of gaseous nitrous oxide were eventually extended up through 1.5 THz [161]. The data set included ground state, ν_2 , $2\nu_2$, ^{15}NNO , $N^{15}NO$, and $N_2^{18}O$ spectra up to $J = 68$, and improved Hamiltonian parameters derived therefrom.

3.5.5 NMR Spectra of Nitrous Oxide

^{15}N nuclear-magnetic-resonance (NMR) measurements on solid ^{15}NNO showed that the anisotropic chemical shift and intramolecular dipole coupling, molecular reorientation resulted in a change in the nuclear-precession frequency [162]. The rate of combined-translation-rotation jumps in this orientationally ordered solid was followed with two-pulse spin echoes, as well as stimulated echoes. Although the rates and activation energies determined by NMR and previously reported dielectric measurements were similar, they were not equal. The data demonstrated that dielectric measurements monitor in-place, head-tail flips, while NMR follows the slightly slower combined-translation-rotation jumps.

3.5.6 Refractive Index of Nitrous Oxide

The refractive index of liquid N_2O at $T = -90^\circ\text{C}$ (183 K) is 1.330.

The refractive index of frozen nitrous oxide at 16 K at 543 nm is 1.318, as shown in Table 5 above [38].

3.6 Electrical Properties of Nitrous Oxide

The dielectric constant of liquid nitrous oxide at 183 K (-90°C) is 1.97, and the dielectric constant of gaseous nitrous oxide at 293 K (20°C) and atmospheric pressure is 1.001028. The dipole moment of nitrous oxide is 0.1608 Debye. The ionization potential of N_2O is 12.6 eV.

3.7 Magnetic Properties of Nitrous Oxide

The magnetic susceptibility of gaseous nitrous oxide is -0.429×10^6 CGS units.

3.8 Solubility of Nitrous Oxide

3.8.1 Solubility of Gases in Liquid Nitrous Oxide

Liquid nitrous oxide is a good solvent for gases and other liquids. Although nitrous oxide as a rocket oxidizer is often used in a self-pressurizing mode, pressurant gases such as helium or oxygen that are applied to prevent it from flashing prematurely into a solid (due to its narrow liquidus range) would readily dissolve in liquid N_2O and alter its behavior in pumps, valves, cavitating venturi, or other orifices. In one application, the N_2O tank was designed contain pressurized helium in the ullage volume, and this He was to force the N_2O out of the tank, through the metering system, and into a combustor. The N_2O absorbs He, and if the absorbed He is subsequently desorbed

during the flow or metering processes, the metering system may not function properly. Supercritical N_2O , similar to supercritical CO_2 , is an excellent solvent for a wide range of substances.

3.8.2 Mixtures of Liquid Nitrous Oxide with Other Oxidizers

Use of gaseous oxygen as the pressurant for other oxidizers eliminates the need for the expensive helium gas. Oxygen gas is quite soluble in liquid nitrous oxide, thus improving its performance and allowing the saturated solution to be used in a self-pressurizing blowdown mode of propellant expulsion.

Liquid nitrous oxide and liquid oxygen are not miscible over the entire range of compositions and temperatures. Studies have been made at either end of the range of composition, studying the solubility of N_2O in LOX and the solubility of gaseous O_2 in liquid N_2O . Mixtures of nitrous oxide, carbon dioxide, and oxygen have been proposed as oxidizers for Mars mission applications [163].

If nitrous oxide is bubbled into a cooled sample of N_2O_4 , a partially saturated solution will contain 9.5 mass-% N_2O , have a freezing point of $255.7\text{ K} = -174^\circ\text{C}$ and a boiling point of 301 K (28°C) [164]. In a similar test, where it was observed that N_2O bubbles bubbling through cooled N_2O_4 were completely absorbed before they reached the surface, the saturated solution contained 41.5 mass-% N_2O and had a freezing point of 222 K (-51°C) and a boiling point of 306 K (33°C). The absorption of N_2O into N_2O_4 was exothermic, suggesting that some sort of chemical reaction may have taken place in addition to forming a physical solution. Many years later, propellant combinations with mixtures of N_2O and N_2O_4 containing between 28 and 52 mass-% N_2O_4 were again patented [165], but there was no reference to prior art such as that described in [164].

3.8.3 Solubility of Nitrous Oxide in LOX

The solubility of nitrous oxide in liquid oxygen will be discussed in detail in *Encyclopedia of Oxidizers*, chapter “Oxygen”.

3.8.4 Solubility of Oxygen in Liquid Nitrous Oxide

Mixtures of gaseous nitrous oxide and gaseous oxygen are widely used in surgery as an anesthetic/analgesic because it was found to be desirable to store the premixed gases in gaseous form in a single cylinder instead of having to meter the two gases from two different cylinders at the point of end use. In a commercial cylinder containing nitrous oxide and oxygen at 293 K (20°C) and a total pressure of 13.8 MPa (136 atm), the maximum percentage of nitrous oxide that can be obtained without the condensation of liquid nitrous oxide is 37% N_2O by volume. For the medical application, it is important that the mixture ratio of the two gases remain the same over the entire period of drawing gases from a cylinder. The nominal composition for anesthesia/analgesia usage is a 50 : 50 mixture by volume of the gases. The composition of the gas mixture

released from evaporating liquid in cylinders that have been stored at low temperatures may deviate from the nominal mixture ratio if the cylinders have not been stored and oriented properly. It is essential that the mixture remain in a homogeneous state during the administration at all times. If liquid N_2O were inside the cylinder, then an oxygen-rich gas mixture would be withdrawn at first, the mixture becoming progressively richer in nitrous oxide until the oxygen concentration fell below 10%. Such a mixture would be dangerous to breathe as it would contain insufficient oxygen to support normal respiration. It was necessary to establish safe procedures for the storage and use of premixed nitrous oxide-oxygen mixtures to prevent phase separation. Unwanted condensation of liquid nitrous oxide may occur inside the full cylinder if it is cooled to a temperature less than about 266 K (-7°C). In the case of premixed cylinders of a 50/50 gaseous nitrous oxide-oxygen mixture used as an analgesic, any liquid phase formed as a result of inadvertently cooling the cylinder to below 233 K (-40°C) can be dispersed and rehomogenized by storing the cylinder horizontally for at least 24 h at a temperature not less than 278 K (5°C). Rolling the cylinder would aid the mixing, and the mixing time is of the order of minutes.

In 2009, a review was undertaken of existing literature to examine the developmental history of these $\text{N}_2\text{O}/\text{O}_2$ mixtures and to examine data to support the position that the contents of a cylinder of a 50 vol.-% nitrous oxide and 50 vol.-% oxygen mixture is in a homogenous single gas phase in a filled cylinder under normal conditions of handling and storage. If phase separation could be made to occur by inadvertent undercooling, there was justification for the instructions given recommending 48-h horizontal storage at temperatures above 283 K (10°C) and repeated inversion of the cylinders before use [166].

The liquid-vapor equilibria for the nitrous oxide/oxygen system have been compared to the behavior of carbon dioxide/oxygen because N_2O and CO_2 are usually very similar in their physical properties and solvent characteristics. The liquid-vapor equilibria for the systems nitrous oxide-oxygen and carbon dioxide-oxygen were measured and presented in the form of isotherms on pressure-composition graphs, and isobars on temperature graphs, up to 20.7 MPa (200 atm) [167]. In Figure 33, the points of known liquid composition give the “liquid curve” or bubble-point curve. If one of these points is approached from outside the loop, it gives the point where the first bubble appears. When the mol fraction of oxygen is zero, the bubble-point and dew-point curves meet at the vapor pressure for pure nitrous oxide at the temperature of the isotherm. The broken line in Figure 33 adjacent to the vapor curve represents the ideal vapor phase composition, assuming that the vapor phase is a mixture of perfect gases obeying Dalton’s law. This assumes that the vapor pressure of nitrous oxide remains constant and independent of the total pressure in the cylinder. In practice, the partial pressure of nitrous oxide found in the vapor phase of these mixtures always exceeded that of pure nitrous oxide. Above a certain pressure, PM (approximately 9.6 MPa (94 atm)), the percentage of nitrous oxide increased rather than decreased as the pressure was raised. This resulted in the liquid and vapor phase compositions be-

Figure 33: 273 K isotherm for nitrous oxide-oxygen mixtures. (Republished and modified from [167], with permission of IOP Publishing Ltd.; permission conveyed through Copyright Clearance Center, Inc.)

coming equal at a critical point. A horizontal line drawn on the pressure-composition diagram connects positions of equilibrium and is called a “tie-line”.

Measurements taken over a temperature range from 243 to 303 K (−30 to 30 °C) in 5° increments were combined in isobars in a temperature vs. composition plot (Figure 34).

Nitrous oxide that is intended to be used as an anesthesia/analgesia agent must be of extreme purity, and contaminants like nitrogen and methane must be removed. The liquid/vapor equilibria of the binary systems N_2O/N_2 , N_2O/O_2 , and N_2O/CH_4 at low temperatures between 213 and 293 K (−60 and +20 °C) and high pressures up to 9.09 MPa (90 atm), bordering on critical point conditions, were measured to identify the range of compositions where purification by distillation is no longer effective [168]. The same measurements also identified the composition/temperature/pressure ranges where N_2O/O_2 gas mixtures might liquefy and disturb the required composition of the gas mixture withdrawn for medical purposes.

With the advances in computational chemistry it has now become possible to predict miscibility and phase boundaries of binary mixtures of nitrous oxide and oxygen. Simulations have been carried out at five different temperatures based on a Lennard-Jones plus point charge functional form [61]. Figure 35 shows the phase equilibrium data at 253.15 K. The simulations were in good agreement with the experimental data

Figure 34: Liquid-vapor equilibrium isobars for nitrous oxide-oxygen mixtures. (Republished and modified with permission of IOP Publishing Ltd. from [167]; permission conveyed through Copyright Clearance Center, Inc.)

in the lower pressure regime. At higher pressures deviations occur for the bubble line. Simulations carried out for pressures higher than 80 bar followed the course of the Bracken et al. isotherm, although the deviations from the experimental data became larger.

The former Space Propulsion Group (Sunnyvale, CA) had applied for a patent [169] for oxidizers based on refrigerated mixtures of nitrous oxide and oxygen that were called “Nytrox” [170], although the claims in the patent were overly broad and diffuse and should have been narrowed to more specific claims before granting a patent. The potential advantages of mixtures of oxygen and nitrous oxide compared with the pure components are:

- partial self-pressurization possible at high densities (eliminates or minimizes the use of expensive helium)
- improved I_{sp} performance compared to N_2O
- unlike liquid oxygen, not cryogenic; oxidizers at 213 to 233 K (−60 to −40 °C) are much easier to manage.
- potentially lower freezing point compared to N_2O useful for space applications

Using oxygen instead of helium as a pressurant for oxygen in bipropellant or hybrid systems would have the advantage that after all liquid oxidizer is consumed, the pressurant gas can be burned with fuel providing additional impulse (assuming that some fuel is left at this point and that the flow rate of both components can be adjusted to account for the change in the physical state of the oxidizer). If there is any concern that

Figure 35: Pressure-composition phase diagram for the oxygen-nitrous oxide binary system at 253 K. (Republished and modified from [61], with permission of © 2007 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.) Experimental data are represented by open symbols, simulated data by solid filled symbols

the residual gaseous nitrous oxide in the oxidizer tank of an all- N_2O oxidizer system at the end of a mission constitutes a potential explosion hazard, then the dilution with oxygen would substantially reduce this hazard, because oxygen dilution increases the energy required to initiate explosive N_2O decomposition in the gaseous state. Because Nitrox is a two-component and two-phase system, a gelling agent would be needed to maintain a homogeneous emulsion of the two liquids. Fumed silica has been proposed as a gelling agent. The Peng-Robinson equation of state can be used to calculate deviations of real mixtures of N_2O and O_2 from the behavior of ideal mixtures and can be used to predict the PVT phase conditions. Figure 36 shows the predicted density of nitrous oxide/oxygen mixtures as a function of pressure and temperature [171]:

Figure 36: Liquid density as a function of pressure at various temperatures for the O_2/N_2O mixtures. (Reproduced and modified from [171] with permission granted by Dr. Arif Karabeyoglu 29-Apr-2021.)

Figure 37: Oxygen mass fraction in the liquid phase as a function of pressure at various temperatures for two-phase O_2/N_2O mixtures. (Reproduced and modified from [171] with permission granted by Dr. Arif Karabeyoglu 29-Apr-2021.)

For application of the $\text{N}_2\text{O}/\text{O}_2$ mixtures as a rocket propellant, it would be more important to know the maximum amount (mass fraction, not mol fraction) of oxygen that can be dissolved in liquid N_2O at any temperature and pressure. These data are displayed in Figure 37.

Nitrox is composed of equilibrium or non-equilibrium mixtures of nitrous oxide and oxygen [172]. The primary advantages of this system over the pure oxidizers are: 1) self-pressurization capability, 2) high density and density impulse, 3) non-cryogenic operational temperatures, 4) higher I_{sp} performance compared with N_2O , 4) improved safety, 5) efficient gas-phase combustion, and 6) easier development of stable and efficient motors compared with liquid oxygen due to the exothermic decomposition of the N_2O molecule.

3.8.5 Solubility of Other Oxidizers and Contaminants in Liquid Nitrous Oxide

Liquid nitrous oxide is an excellent solvent and will dissolve water and form hydrates. The solubility of water in compressed nitrous oxide was measured over pressure ranges of 0.1–6.08 MPa (1–60) atm and temperatures ranging from 293 to 373 K (20 to 100 °C) [173]. Second cross virial coefficients representing deviations from ideality caused by gas/water pair interactions were more negative than those for water with ethane at all temperatures. For water with nitrous oxide, the anomalously large values of these coefficients were interpreted as indicating that a reversible hydration reaction occurs between nitrous oxide and water vapor in the gas phase

Supercritical N_2O , similarly to supercritical CO_2 , is an excellent solvent for a wide range of substances. So it should come as no surprise that CO_2 and N_2O are totally miscible with each other over the entire range of compositions in the liquid and supercritical range. Energy wise, there is no advantage in diluting N_2O with CO_2 , but safety and physical properties (freezing point) may improve.

Nitrous oxide and carbon dioxide have very similar physical properties. Both are excellent solvents in the supercritical state. Carbon dioxide is not a good rocket propellant oxidizer, we see it more as a combustion product than a rocket propellant oxidizer. In the liquid state, it is totally miscible with nitrous oxide. If there is any need to lower the combustion temperature of nitrous oxide bipropellant or hybrid rockets, or if there is a need to lower the freezing point and widen the liquidus range, one might consider adding just a few percent of carbon dioxide to nitrous oxide. The $\text{N}_2\text{O}/\text{CO}_2$ system has been investigated up to near the critical point because the critical properties of these two gases are very similar. The phase boundaries, orthobaric densities, and critical constants of five mixtures of carbon dioxide and nitrous oxide have been measured between 293 K and the critical point [42]. The same physical properties for the two pure gases have also been measured. The apparatus consisted of a calibrated thick-walled hard-glass pressure tube, fitted with an electromagnetic stirrer, for visual observation of the dew-points, boiling-points, and critical points, plus auxiliary equipment for precise temperature and pressure measurements. The system behaves

almost as an ideal solution with small positive deviations from Raoult's law, which can be interpreted satisfactorily by the theory of conformal solutions. The instruments and techniques used for the study of the $\text{N}_2\text{O}/\text{CO}_2$ system may be useful for the study of the solubility and phase behavior of solutions of other fuels in nitrous oxide.

The excess molar enthalpy, H_m^E , and excess molar volume, V_m^E , of the binary system $[x\text{CO}_2 + (1-x)\text{N}_2\text{O}]$ were measured in both the liquid and supercritical regions over the range 262.4–324.7 K at pressures up to 12.08 MPa [174]. The excess functions at 262.4 K were small, but in the critical region, very large H_m^E and V_m^E were measured. The Patel-Teja equation of state could reproduce all the main features of $H_m^E(x)$ and $V_m^E(x)$ and has been used to generate $H_m^E(p,x)$ and $V_m^E(p,x)$ surfaces at 312.5 K.

3.8.6 Solubility of Fuels in Liquid Nitrous Oxide

The kinetics of gas phase reactions of N_2O with CO have been studied extensively, usually as part of environmental studies of combustion products of energy conversion processes and also in dilution with inert gases [175–178]. This gas mixture may also be used in chemical lasers. Liquid N_2O may be miscible with liquid CO, but the safety properties of such a monopropellant blend would have to be examined before the process is scaled up.

The solubility of N_2O and CO_2 in ionic liquids can be quite different, such that the otherwise difficult to separate gases can be separated by selective absorption into ionic liquids in a countercurrent trickle flow reactor. Solutions of N_2O as the oxidizer in ionic liquids as fuels might be used as monopropellants. Mixtures of nitrous oxide and ethylene are already being evaluated as monopropellants.

The combination of premixed gaseous nitrous oxide and ammonia has been evaluated as a monopropellant for micropropulsion devices, and one version of this concept envisioned storing the two chemicals premixed in the liquid instead of the gaseous state. Insufficient data were available about the range of miscibility of liquid nitrous oxide and liquid ammonia over the entire range of mixture ratios. Experiments were started at the University of Washington in Seattle to fill this data gap but could not be completed because a Phase II STTR contract was not obtained.

In searching the literature, only incomplete information about the range of miscibility of liquid nitrous oxide and liquid ammonia could be found. In one case, a solution of 0.4-M nitrous oxide in liquid ammonia was subjected to electron nanosecond pulse bombardment at temperatures down to 198 K (–75°C) and the UV spectra of the amino free radical recorded [179]. The N_2O served as a scavenger for free electrons dissolved in liquid ammonia.

3.8.7 Solubility of Other Gases in Liquid Nitrous Oxide

When it is to be used as an oxidizer in a pressure-fed rocket system, liquid nitrous oxide does not need a pressurant gas like helium or nitrogen as some of the other oxidizers would. Nevertheless the solubility of pressurant gases in liquid nitrous oxide

has been measured. If a pressurant like helium is used to expel liquid nitrous oxide from a tank, one has more latitude in selecting the discharge rate from the tank without having to worry about inadvertently freezing the tank contents. But unless the gas and the liquid phase are separated by an impermeable diaphragm, some of the pressurant will dissolve in liquid nitrous oxide and reduce its performance and will change the flow rate if the saturated liquid is passing through cavitating venturi as a means of flow rate control. If the saturated liquid is pumped with a centrifugal pump, cavitation may occur at the tips of the rotor.

Liquid-vapor data for the helium-nitrous oxide system were determined at 195, 215, 235, 245, 255, 265, and 285 K at pressures up to 136 bars [180]. The data were analyzed for internal consistency using pseudo-Henry's law constants and enhancement factors. For instance, at 285 K and 136 bar, the liquid phase contained 4.18 mol-% He. At 265 K and 136 bar, the vapor phase contained 25.97 mol-% N₂O. Figure 38 shows the pseudo-Henry's law constant as a function of pressure. Henry's law constant is defined here as

$$H = \frac{P - P_1}{X_2}$$

The helium pseudo partial pressure is defined as $P - P_1$. The constant is nearly independent of pressure. Figure 39 shows the pseudo-Henry's law constant as a function of temperature based on data obtained at 20 and 120 bar. Data for both pressures fitted on a linear relationship.

One of the basic components of many propellant metering systems is a cavitating venturi. This device causes a rather sudden drop in the static liquid N₂O pressure, and there was concern that this sudden pressure drop would cause helium desorption from the liquid. If such desorption and two-phase flow occurred, the gaseous helium would tend to choke the flow of liquid N₂O through the venturi throat and, thereby, interfere with proper functioning of the metering system. Calculations indicated that significant choking would occur if equilibrium conditions prevailed. In order to determine the effect of helium on flow choking, flow tests were run using both saturated and unsaturated N₂O. It was found that the flow rate of the helium-saturated N₂O was 9 to 12% lower than that of the unsaturated liquid [181]. The flow of saturated N₂O through the venturi is neither equilibrium flow nor frozen flow but is rather something in between the two. Thus, there is some effect due to helium desorbing from the liquid N₂O, but the effect is much less than that predicted for equilibrium flow conditions.

Under an AFWL contract Rocketdyne conducted full-scale N₂O flow tests and measured flow rates with both turbine flow meters and cavitating venturi [92, 182]. The oxidizer flow rate to the combustor was controlled by a cavitating venturi located between the main valve and the primary injector. This was a 5-cm (2-in.) variable area unit in which the throat area was modulated by the position of a movable pintle. The venturi was calibrated with gaseous nitrogen to obtain a curve of effective throat area as a function of pintle position. In parallel, nitrous oxide flow rates in all these tests were

Figure 38: Pseudo-Henry's law coefficient of helium in liquid nitrous oxide as a function of pressure. (Reproduced and modified from [180].)

measured with turbine flowmeters. On the basis of the measured flow rates, the effective throat area of the cavitating venturi was calculated in each case. When plotting N_2O results together with the GN_2 calibration curve, all flows of neat N_2O fell on a line which was slightly displaced from the calibration curve. When the N_2O was (partially) saturated with helium, however, the effective throat area of the cavitating venturi was a function of the proportion of helium dissolved.

Another pressurant gas of interest for nitrous oxide is oxygen. Mixtures of liquid nitrous oxide and liquid oxygen ("Nytrox") have been proposed as oxidizers for rockets [172], see Section 3.8.4.

4 Chemical Properties of Nitrous Oxide

4.1 Reactions with Nitrous Oxide

Nitrous oxide is not very reactive as an oxidizer and will react hypergolically only with very few fuels at room temperature. Reactions of industrial importance are the production of sodium azide by reaction of molten sodium amide with nitrous oxide:

Sodium azide can also be formed in the reaction of N_2O either with metallic sodium dissolved in liquid ammonia

or with sodium oxide dissolved or suspended in liquid ammonia

The reaction of N_2O with ammonia over a $\text{Ni-Al}_2\text{O}_3$ catalyst can form ammonium azide, which is potentially explosive:

It has been speculated that oxidation of ammonia by nitrous oxide under carefully controlled (non-combustion, catalyst) conditions may even result in the formation of hydroxylamine. If premixed nitrous oxide and ammonia were to be used as a monopropellant, the above reactions would be very undesirable since they would detract from the storage stability of the premixed propellant.

Nitrous oxide containing 96% ^{15}N in the end position and analysis of the reaction products by mass spectrometry was used to determine in which combustion reactions with N_2O the oxygen is stripped from the end of the molecule, leaving the $\text{N}-\text{N}$ bond and the $^{15}\text{N}:^{14}\text{N}$ ratio intact, and in which reactions a complete rearrangement and equilibrium between the three possible dinitrogen isotopologues is achieved [183].

A good summary of the chemical reactions of all nitrogen oxides including nitrous oxide was published in 1972 [184]. The literature review by Leontev [1] contains a good summary of chemical reactions with nitrous oxide [1].

Nitrous oxide for non-anesthetic applications has to conform to Specification MIL-N-37996.

4.2 Conversion of Nitrous Oxide to Other Oxides of Nitrogen

The diagram in Chapter Nitrogen Oxides, Section 2.5 already illustrated that nitrogen oxides readily undergo conversions into each other, depending on the conditions. Oxidation of nitrous oxide in the stratosphere leads to nitric oxide [185].

4.3 Selective Oxidation Reactions with Nitrous Oxide as an Oxidizer

The decomposition of nitrous oxide leads to atomic oxygen as an intermediate, which is a very reactive species that can be used in the oxidative hydroxylation of aliphatic or aromatic hydrocarbons, leading to alcohols, ketones, or phenols. A large industrial plant for the production of 140000 tons of phenol using this process has been built

in Florida. However, attempts to convert methane to methanol by oxidation with N_2O have failed.

4.4 Decomposition, Thermal Stability, and Combustion of Nitrous Oxide

The decomposition of nitrous oxide as a monopropellant in rocket engines is discussed in detail in *Encyclopedia of Monopropellants*, in the chapter Nitrous Oxide Monopropellants. Here, we only discuss academic studies on N_2O decomposition that are not related to a specific application but support the development of N_2O monopropellant decomposition reactors and help explain the hazards caused by unexpected N_2O explosions.

Because nitrous oxide absorbs infrared radiation from the sun, similarly to carbon dioxide in the atmosphere, it acts as a “greenhouse gas” potentially contributing to global warming. It was estimated that the average residence time of nitrous oxide in the lower layers of the atmosphere is 120 years because of the lack of reactions or biological cycles that would lead to its consumption. Nitrous oxide gradually diffuses from the troposphere to the stratosphere where it eventually becomes photolyzed by UV from the sun. Until recently, large amounts of nitrous oxide were dumped with stack gases from industrial processes like nitric acid production, released as an unwanted byproduct of the industrial fossil fuel combustion processes, as an intermediate in air pollution, and as an industrial waste product during the production of nitric acid [186] and caprolactam or adipic acid [187] and cyclohexanone oxime (“Nylon”) production. It has been estimated that annually about 1.2 million tons of N_2O are emitted by the nitric acid industry, which is equivalent to the CO_2 emissions of 80 million passenger cars. The problem with nitrous oxide as an atmospheric pollutant is that there are very few natural mechanisms that will destroy nitrous oxide once it is released into the atmosphere (as opposed to carbon dioxide, which can be assimilated by plants and immobilized into the shells of crustaceans). The chemical industry has taken steps to minimize emissions of nitrous oxides by changing chemical processes and passing stack gases through N_2O decomposers before releasing them above the roof. Studying the decomposition N_2O as a monopropellant and looking for catalysts will direct one quickly to the large amount of literature dealing with catalytic decomposition of N_2O in industrial waste gases. However, these processes operate at much lower temperatures than a rocket engine, and most of the catalysts studied for waste gas cleanup are not suitable for use in a rocket engine. The catalytic decomposition of N_2O will be discussed in *Encyclopedia of Monopropellants*, chapter “Nitrous Oxide Monopropellants”. A partial discussion of the homogeneous decomposition of nitrous oxide in the gas phase is started here because homogeneous decomposition in the gas phase often precedes the decomposition of nitrous oxide before it has a chance to come in contact with a catalyst. The homogeneous decomposition rates are just so much slower than the catalyzed decomposition rates that they are often neglected when conducting experiments with active catalysts.

4.4.1 Kinetics of Nitrous Oxide Decomposition

Early work has shown that nitrogen atoms are not formed during the N_2O decomposition process, which indicates that the decomposition takes place via the break-up of the N—O bond. The following three reactions, each corresponding to a different electronic state for the atomic oxygen formed as an intermediate, are possible:

The measured activation energy for the nitrous oxide decomposition of approximately 243 kJ/mol (58 kcal/mol) rules out the last two reactions, which require significantly more energy. This indicates that the decomposition of nitrous oxide follows the non-adiabatic spin-forbidden elementary unimolecular reaction, which requires a change in the multiplicity, from the singlet ground state for the N_2O molecule to a triplet state in atomic oxygen, which is a spin-forbidden transition in quantum mechanics and may be one of the causes for the abnormally slow unimolecular reaction rate for N_2O decomposition. Due to its unique spin-forbidden nature and also the relatively simple structure of N_2O , the decomposition reaction has been the subject of many theoretical studies. In the recent literature, an extensive number of classical and quantum mechanical molecular dynamics simulations have been reported. The primary objective of these studies has been to gain more insight on the spin-forbidden unimolecular decomposition of the nitrous oxide molecule and other nitrogen oxides.

The experimental and theoretical absolute rates for the non-adiabatic, homogeneous decomposition of N_2O were shown to be in good agreement [188]. There are only a few other reactions involving singlet-triplet transitions of oxygen, which can be compared to the spin-forbidden N_2O decomposition. A convenient method of constructing potential functions for polyatomic molecules which fit the spectroscopic data, and which apply in a proper way for the various dissociation processes, was developed for the N_2O molecule as an example for the utility of this method.

For a first-order reaction of a homogeneous gas phase reaction, a plot of the reciprocal of the half-reaction time against pressure should be a line parallel to the pressure axis, while for a second-order reaction it should be a line inclined to the axis and passing through the origin. In a series of investigations, it has come to light that the form of this curve for nitrous oxide is really rather complex, and may be divided into the following parts: (a) an initial steep increase, starting from the origin, which between 50 and 100 mm Hg becomes shallower and passes into (b) an almost linear curve continuing up to several atmospheres of pressure when it gradually bends again passing into (c) an almost straight line of still smaller slope, which continues up to 20–30 atm, when it bends round and becomes nearly parallel to the pressure

axis, as one would expect for a reaction of the first order [189, 190]. Various interpretations have been suggested: **(1)** The twisted curve results from the superposition of three “quasi-unimolecular” reactions, each of the second order at low pressures and of the first order at higher pressures (typical of reactions in which activation is by collision and is followed by transformation of isolated molecules). The three components represent different activation modes with different transformation probabilities of the activated molecules. **(2)** The curve is not really composite in form, but represents a single quasi-unimolecular reaction, the transformation probability of the molecules being a continuous function of the excess energy they contain. Experimental data of the thermal decomposition of nitrous oxide at 1020 and 925 K (747 and 652°C) where the variation of reaction rate with pressure was expressed both in terms of the reciprocal half-reaction time and in terms of the initial rates showed that the two curves obtained were similar enough to show that previous conclusions based upon the half-time curve are proven correct. The mean value of the activation energy decreased at lower pressures, and the absolute magnitude of this energy agreed with most previous determinations, but not with those suggesting that the reaction is abnormally slow for certain quantum-mechanical reasons.

In a study of the role of nitric oxide in the decomposition of nitrous oxide it was found that although initial yields of nitric oxide were as high as 50–60%, the nitric oxide quickly inhibited its own formation [191].

The mechanism proposed by Lindars and Hinshelwood was later modified by considering the potential energy diagram of N_2O by proposing that the two intermediate triplet states suggested by them are the unstable $^3\Sigma$ and $^3\Pi$ states [192]. This hypothesis satisfactorily accounted for the changes in the first-order decomposition rate constant with pressure. The kinetics of the formation of nitric oxide as an intermediate needs additional explanation. The oxygen atoms formed by the primary dissociation of nitrous oxide will possess a considerable amount of kinetic energy, and it was suggested that, as a result, they will have a greater chance of reacting with another nitrous oxide molecule to give nitric oxide. This accounts for the effect of inert gases, surface area, and temperature on nitric oxide formation. The reaction of nitric oxide with oxygen atoms accounts for the way in which nitric oxide inhibits its further formation. The thermal decomposition of nitrous oxide via nitric oxide produces mainly nitrogen and oxygen.

On the basis of experimental data on the ignition temperatures of pure nitrous oxide flow with $p = 0.3\text{--}4.1$ MPa, and using the equation given by the ignition theory of Zeldovich, the reaction order and the Arrhenius parameters for the process of thermal decomposition of N_2O was calculated [193]. For $p > 0.7$ MPa, good agreement with the established values recommended in the literature was observed. Lower values of the effective activation energy were found for lower N_2O pressures. This may be due to the influence of a heterogeneous catalytic surface.

The thermal, homogenous dissociation of N_2O was measured in dilution with three different carrier gases in a laminar flow reactor in the temperature range

1000–1350 K and at atmospheric pressure in order to determine activation energy and third body efficiency of N_2 [194]. A rate constant for the reaction

of

$$4.0 \times 10^{14} \exp\left(\frac{-28230}{T}\right) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

was recommended with an estimated uncertainty factor of 1.5 in the 1000–3000 K range. The third body efficiency for N_2 compared to Ar was determined to be 1.6, independent of temperature, while the collision efficiency of He apparently increased with temperature, from 2.3 at 1200 K to 4.5 at 2000 K. In terms of a pseudo first-order reaction, the data with N_2 as the carrier gas could be represented by the rate constant

$$k = 4.2 \times 10^9 \exp\left(\frac{-27000}{T}\right) \text{ s}^{-1}$$

The uncertainties associated with the flow reactor technique have been analyzed, and flow reactor studies on N_2O dissociation were examined and compared with recent results. The thermal dissociation of N_2O compared to other decomposition mechanisms in fluidized bed combustion is important.

A detailed N/O kinetic mechanism has been developed and tested in comparison with experimental data for N_2O ignition, NO and NO_2 decomposition at high temperatures [195]. It consisted of 27 reactions among 11 species. A sensitivity analysis revealed which reactions are critical for the quality of the modeling in comparison to experimental results. The proper choice of the rate constants for these reactions can result in good agreement for the ignition delays in the pure N_2O and its mixtures with Ar, and decomposition rates of NO and NO_2 in static reactors and behind shock waves. The modeling also tested controversial rate constants for the key reactions

and

and demonstrated that the use of too low or too high values of the rate constants was incompatible with experimental data.

Nitrous oxide decomposition in the temperature range 1100 to 1600 K at atmospheric pressure was studied in a quartz flow reactor externally heated in an electrical furnace with mixtures of N_2O /Ar, N_2O /H₂O/Ar and N_2O /CO₂/Ar [196]. Based on these experiments and the modeling of a one-dimensional flow reactor, the kinetic parameters of the reaction

for Ar, H₂O and CO₂ as a third body M were determined. The relative efficiencies compared to Ar were found to be 3.0 for CO₂ and 10.0 for H₂O.

4.4.2 Quantum Mechanical Aspects of Nitrous Oxide Decomposition

A classical trajectory surface-hopping energy potential study of the effects of initial mode of excitation on the spin-forbidden predissociation of N₂O revealed a certain mode specificity [197]. Incomplete energy randomization together with significant variation in energies of the surface crossing points with molecular geometry can lead to changes in the accessibility of the dissociation channel and, hence, the rate of reaction when different modes are excited. The variations in the predissociation rate are most marked at relatively low energies. At higher energies, although energy randomization is still incomplete, there is less dispersion in the rate constants. This has been attributed to the fact that at high energies a larger percentage of the crossing points become accessible, and thus the directionality of the initial motion is less relevant to the rate. Finally, it was shown that in cases where the surface-hopping probability is low, the kinetics of spin-forbidden reactions will be characterized by unusually unfavorable entropies of activation. As a consequence, reactions involving a spin-state change can be expected to compete poorly with spin-allowed reactions at high temperatures (or energies); see also Reference [198].

The spin-forbidden predissociation reaction of the ground-state N₂O was studied by quantum dynamics *ab initio* calculations to obtain the potential energy surfaces of the singlet ground state of N₂O and three triplet states correlating with the asymptote N₂ + O(³P) and the spin-orbit coupling elements among them [199, 200]. The decay rate of individual singlet vibrational state to the ³A' state was estimated by applying the Fermi golden rule. For the ¹A' state, a total of 1692 vibrational eigenstates with even parity for the total angular momentum $J = 0$ were obtained, and time-dependent wave packet calculations on the triplet potential energy surfaces were performed to obtain the autocorrelation functions whose Fourier transforms should provide the decay rates. The resultant decay rates for 887 singlet vibrational states in the energy range $67.3 \leq E \leq 83.7$ kcal/mol were analyzed in terms of a random matrix/transition state theory. The analyses of calculated decay rate distributions indicated an incomplete energy randomization of the vibrational energy in the singlet state even near the singlet state dissociation threshold.

Molecular dynamics model calculations for the thermal decomposition of N₂O with an external magnetic field suggested that the increase of the rate constant by an external magnetic field could be explained by means of an increase of the interaction term, which is dependent on the angle of orientation [201]. The magnetic field would orient the molecules in a position more favorable to interact with partners. Lowering the onset temperature of exothermic decomposition on a catalyst by applying a magnetic field would facilitate the use of nitrous oxide as a monopropellant.

4.4.3 Flame Velocity of Gaseous Nitrous Oxide Decomposition

Decomposition flames of nitrous oxide in the absence of a fuel are discussed in *Encyclopedia of Monopropellants*, chapter “Nitrous Oxide Monopropellants”. The rate of propagation of N_2O decomposition flames in closed tubes (“flashback”) must be measured before designing rockets with N_2O . Similar measurements have been made for flames supported by premixed combustible gases with N_2O as the oxidizer. Essentially, at the very lean end of the range of O:F ratios studied, the flame is mostly an N_2O decomposition flame.

4.4.4 Autoignition Temperature of Nitrous Oxide in the Absence of Combustibles

The autoignition of nitrous oxide by simple heating in the absence of combustible materials or a spark or open-flame source of ignition was determined in steel tubes [92, 202]. Nitrous oxide autoignition tests were conducted by preheating a steel pipe to the desired temperature and then suddenly opening the inlet valve to permit high-pressure 5.52 MPa (800 psig) N_2O at rising pressure to flow into the test pipe until the pressures equalized, and the flow stopped. Two different supply systems were used. One was fed through a 12-mm (1/2-in.) diameter tube from a bank of five N_2O bottles to produce a relatively high pressurization rate, and the other was fed through a 6-mm (1/4-in.) diameter tube and pressure regulator to provide slower pressurization rates. No autoignitions were obtained in the 25-mm (1-in.) pipe. The data for the 50-mm (2-in.) diameter pipe showed a trend of decreasing pressurization rate with increasing pressure. At 505 K (450 °F) pipe preheat temperature, autoignition occurred at a pressurization rate of only 1.38 MPa/s (200 psi/s). This is extremely low compared to pressurization rates commonly used in pneumatic systems. Even at ambient temperature, N_2O ignition occurred at a rate of only 7.93 MPa/s (1150 psi/s). This is surprising because the compressed gas also loses heat to the wall of the pipe. It was estimated that autoignition occurred somewhat below 672 K (750 °F). A correlation was developed to express the quenching-controlled propagation limits in terms of pressure, temperature, and pipe size:

$$1.1 \times 10^9 = PT^{2.5} \frac{D^{-2}}{(D - 0.38)}$$

where P is the pressure in psia, T is the temperature in °R, and D is the internal diameter in inches. A comparison of autoignition temperature versus pressure limits is shown in Figure 40.

The data in Figure 40 show that pipe diameter, along with pressure and temperature, is a significant variable. The effect of pipe diameter indicates the important role of quenching in inhibiting the ignition and autodissociation reaction. As the pipe diameter decreases, the surface to volume ratio of the pipe increases. Thus, if decomposition in a small pipe is compared with that in a larger pipe, the surface to volume

Figure 40: A comparison of autoignition temperature versus pressure limits of nitrous oxide autoignition. (Reproduced and modified from [92].)

Symbols legend: PWA [202] data; Ohio State [203] data

ratios indicate that a greater fraction of the heat released by the dissociation will be to the environment from the small pipe than from the large pipe. This heat loss tends to quench the reaction and, as a result, higher temperatures and pressures are required to initiate and sustain a decomposition reaction in a small tube

A theoretical model of gaseous nitrous oxide autoignition and an induction period as a function of pressure and reactor volume showed that for a large vessel under adiabatic (no heat loss) conditions, the predicted autoignition temperature is in the range 670–700 K [204] (Figure 41). Dilution with oxygen shifts the curves only very little to the right.

During the induction period, the reactions are slow, and the temperature slowly increases up to the overheating limit, where a runaway reaction takes place, often in an explosive manner (Figure 42).

4.4.5 Explosive Decomposition of Nitrous Oxide in the Absence of Combustibles

The explosion hazards of nitrous oxide will be discussed in more detail in Section 9.2. Here, we only discuss some of the mechanisms that lead to a self-propagating reaction in the gas phase.

The initiation of explosions in gaseous nitrous oxide in different sized heavy-walled containers and with different sources of ignition was studied over the pressure range from 0.05 to 8 bar [205]. Generally, the pressure rise curve in a closed container was measured, but in a few cases, the reaction was filmed with a high-speed camera, and the reaction products were analyzed by gas chromatography (GC). The ratio of explosion peak pressure to initial pressure increased with pressure. Due to the relatively slow rate of decay of nitrous oxide, the type and location of the source of ignition and the size of the container had a pronounced effect on the rate of reaction and the fraction of gas decomposed. The required dilution with oxygen, nitrogen, or air as diluents required to prevent an explosive decomposition reaction was determined. For all three gases, a diluent concentration of 30 vol.-% was sufficient to prevent explosions. In a container with saturated liquid/gas conditions, the decay could no longer be initiated when the temperature was below 218 K (-55°C), and the vapor phase pressure was below 5.7 bar.

A stainless steel cylindrical bomb, 61 mm I. D. and 545 mm long, with five windows at equal intervals along the length of the bomb, was used to study the explosive limits in gaseous nitrous oxide [206]. The nitrous oxide was ignited by short-circuiting the current from a 220 V/12 V transformer across a 0.2–0.3-mm diameter copper wire, placed at one end of the bomb. The ignition limit was at 2.63 ± 0.08 bar, at an initial temperature of 290 K, when the bomb was placed vertically, for bottom ignition. This value was unaffected by an increase in ignition energy by a factor of 10 or by creating isobaric conditions, using a ballast vessel, filled with nitrogen. When ignition was made to occur at the top end of the vertically placed bomb, the value of the ignition limit increased to 11.1 bar (absolute). An experiment at high initial pressure of 50 bar resulted in the destruction of the heavy-walled apparatus. Testing the effect of nitrogen as a diluent it was found that 4.5 and 10% nitrogen diluent resulted in higher limit pressures of 3.19 and 5.57 bar, respectively, both at 290 K.

The explosive decomposition of nitrous oxide was studied in the temperature range 323 to 398 K, at initial total pressures up to 13.8 bar (gauge) [207]. The flanged vessel was cylindrical in shape with an internal volume of 2.522 L and an internal diameter of 4.5 inches (114.3 mm). It was constructed of stainless steel and designed to withstand dynamic pressures of up to 105 bar. Ignition was with a coiled electrically heated exploding nichrome wire providing 30 mJ. Stainless steel liners could be inserted to reduce the internal volume and diameter of the bomb. Different wire lengths and thicknesses were tested, and best results were obtained with a wire 1.4 in.-long 24 gauge thickness. In addition, the internal volume to surface area ratio of the pressure vessel was varied by the use of suitable liners. The flammability limits for pure nitrous oxide are shown in Figure 43. The ignition limit varied from

7.93 bar (gauge) at 298 K to 2.41 bar (gauge) at 473 K, on an exponential S-shaped curve. With the heavier liner that reduced the internal volume to 300 mL, only partial decomposition could be achieved. The use of nitrogen, as an inert diluent, to suppress the explosive decomposition of nitrous oxide was studied in the temperature range 323 to 398 K, at initial total pressures up to 13.8 bar (gauge). Nitrogen acted as an inert diluent in suppressing the explosive decomposition of nitrous oxide. The amount of nitrogen required to suppress the decomposition was a function of initial temperature and pressure. The effect of initial pressure on the burning velocity, calculated from the P-t record, and the effect of initial pressure on the amount of inert diluent required to suppress decomposition, indicated that the decomposition of nitrous oxide is a first-order reaction.

Figure 43: Explosion limit of nitrous oxide with exploding wire ignition. (Reproduced and modified from [207].)

4.5 Photolysis of Nitrous Oxide

Photolysis of nitrous oxide in the stratosphere under the action of unfiltered sunlight is the prime mechanism for the destruction of nitrous oxide and prevention of its buildup and becoming a greenhouse gas global warming problem. Consequently, the photolysis of nitrous oxide has been thoroughly investigated. Ultraviolet radiation not only decomposes nitrous oxide, but on irradiating a mixture of nitrogen and oxygen, some nitrous oxide is formed in reversal of the photolysis reaction.

In addition, the photolysis of nitrous oxide is a convenient source of atomic oxygen, which then can be used for other chemical reactions and kinetics studies. It is possible that laser photolysis of nitrous oxide in a rocket engine could be used for ignition of nitrous oxide or nitrous oxide/fuel mixtures, but if it is feasible, then the photolysis of nitrous oxide must be better understood to build a reliable laser ignition device.

The average quantum yields during the photolysis of nitrous oxide in a flow system at 1470, 1295, 1236, or 1165 Å with regard to decomposed nitrous oxide were found to be larger in the experiments using the longer wavelengths than in the experiments using the 1236 and 1165 Å radiation [208]. It was assumed that at 1295 Å the initial absorption of a light quantum leads to the production of nitrogen molecules and oxygen atoms. At the shorter wavelength, the initial absorption act probably proceeds in a dual manner where competitively both the splitting of nitrous oxide into nitrogen molecules and oxygen atoms and into nitrogen atoms and nitric oxide might occur at this wavelength.

Oxygen atoms in the singlet 1S state can be produced by the vacuum-UV photolysis of N_2O . and their emission can be observed at 5577 Å in the $^1S \rightarrow ^1D$ transition [209]. The stimulation of this emission by collision with added gases has been studied. The emission was found to be proportional to the pressure of the added gas. Xenon is the most efficient stimulator of the gases used, followed in order of decreasing efficiency by Kr, Ar, N_2 , H_2 , and He.

Photofragment ion imaging has been used to study the $O(^1D_2)$ atoms produced in the ultraviolet (~ 200 nm) photodissociation of nitrous oxide in a molecular beam [210]. The images of $O(^1D_2)$ revealed a speed-dependent angular distribution resulting from both variation in the spatial anisotropy of the recoil and alignment of the electronic angular momentum of the $O(^1D_2)$ fragment. The orbital alignment effects were revealed by a change in the images when different transitions of the O atom are employed in the resonance enhanced multi-photon ionization process.

Laser photolysis was proposed as an efficient method for removing N_2O in stack gases at atmospheric pressure and at room temperature without using any catalysts. N_2O diluted in N_2 or air was decomposed into N_2 , O_2 , and NO by using a 193-nm ArF excimer laser [211, 212]. The maximum conversion of N_2O in N_2O/N_2 or $N_2O/N_2/O_2$ mixtures was 93% at a laser power of 136 mJ, a repetition frequency of 5 Hz, and an irradiation time of 30 min. The formation ratios of $N_2:O_2:NO$ in N_2O/N_2 and $N_2O/N_2/O_2$ mixtures were 64 : 31 : 5.1% and 60 : 27 : 13%, respectively.

N_2O removal was investigated in N_2 or air using 172-nm Xe_2 excimer lamps (50 or 300 mW/cm²) without using any catalysts [213]. The residual amount of N_2O and the formation ratios of products were measured as functions of irradiation time, N_2O concentration, and O_2 concentration. N_2O (100 ppm in N_2) was completely converted to N_2 and O_2 without NO_x emission at atmospheric pressure after 30 min photoirradiation using a high-power Xe_2 excimer lamp (300 mW/cm²). The conversion of N_2O in air increased more than twofold by decreasing the total pressure from atmospheric pressure

to 20 kPa by suppressing the collisional quenching of $O(^1D)$ by N_2 and O_2 buffer gases. In a flow experiment with a total flow rate of 0.1–1 L/min., the conversion of N_2O/N_2 was only 6–18% due to the short residence time of N_2O in the photolysis chamber; see also [214, 215].

Photodissociation of nitrous oxide near 203 nm has been studied by a combination of a high-resolution slice ion imaging technique and resonance-enhanced multi-photon ionization spectroscopy by measuring the recoil velocity and angular distributions of N_2 fragments by ion images of the state-resolved photofragments to verify the effects of the stagnation pressure on the formation of N_2O clusters and their photodissociation in the UV [216]. Slice imaging is characterized by a delayed pulsed extraction of ions. The N_2 fragments were highly rotationally excited, and the $NN-O$ bond dissociation energy was determined to be 3.635 eV. In addition, photofragment images from the photodissociation of N_2O clusters at various stagnation pressures provided information on the affinity attraction of N_2O molecules in clusters.

Photolysis of N_2O in an argon matrix deposited on an IR-transparent window resulted in formation of N_2O_2 having the structural formula $O-O-N-N$, which has been named asymmetric dinitrogen dioxide [217]. The experiment was conducted under vacuum with a flowing gas pressure between 10^{-5} and 10^{-4} mm Hg. Argon was used as the non-reactive matrix. A gas stream of one part by volume N_2O and 400 parts by volume argon was directed to a cooled CaF_2 window maintained at a temperature between 8 and 20 K. The gas stream condensed to form a solid N_2O/Ar layer on the surface of the window. Oxygen atoms in the $[^1D]$ excited state were generated by photolysis of a portion of the condensed N_2O with UV radiation pulses of 15 ns duration at a repetition rate of one hertz, having an intensity of about 100 mJ at a wavelength of 193 nm using an excimer laser. A tunable IR source was directed through the window to a monochromator, and IR absorption spectra were monitored and recorded. An absorption peak at a frequency of about 1220 cm^{-1} , which falls within the region of the predicted $N-O$ stretch frequency for asym- N_2O_2 , was present only after irradiation.

4.5.1 Photocatalysis of Nitrous Oxide Decomposition

In addition to photolysis of N_2O in homogeneous reactions in the gas phase, photocatalytic decomposition of N_2O on illuminated catalytic surfaces has received a lot of attention as a possible method for destruction of N_2O in industrial waste gases. This seems to be a symbiotic combination of both photolysis and catalytic decomposition of nitrous oxide.

Photodecomposition of N_2O under irradiation with UV light ($\lambda < 300\text{ nm}$) at room temperature readily proceeds on the surfaces of transition metal oxide compounds applied to inert supports. Ions of different transition metals in zeolite matrices exhibit high catalytic activities.

An Ag(I)/ZSM-5 catalyst containing highly dispersed Ag ions on ZSM-5 exhibited much higher photocatalytic reactivity for the decomposition of N_2O than Ag(I)/Y formed on Y-zeolites, indicating that highly dispersed Ag ions play a significant role in the photocatalytic decomposition of N_2O [218, 219].

The photocatalytic decomposition of N_2O on highly dispersed distorted tetrahedrally coordinated Fe-oxide on ZSM-5 having low Si/Al ratios proceeded with a good linearity against the UV-irradiation time [220]. The photocatalytic efficiency decreased when the Si/Al ratio was increased; see also [221, 222].

4.6 Radiolysis of Nitrous Oxide

Radiolysis of nitrous oxide might be one way to synthesize higher oxides of nitrogen, which might be better oxidizers than N_2O . Radiolysis of nitrous oxide might also occur in nitrous oxide propellant tanks in outer space under the impact of cosmic radiation. Radiolysis of nitrous oxide in the upper stratosphere under the influence of cosmic radiation might be one loss mechanism that converts N_2O to dinitrogen and dioxygen or to other nitrogen oxides. So there are multiple reasons why radiolysis of nitrous oxide is being investigated here [223, 224]. Nitrous oxide acts as a hydrogen atom scavenger [225]. Nitrous oxide reacts with electrons rather than hydrogen atoms in liquid hydrocarbons. The radiolysis of pure liquid nitrous oxide and of nitrous oxide/cyclopentane solutions were investigated [226].

The radiolytic decomposition of nitrous oxide has been proposed as the basis of a dosimeter, where the amount of nitrogen formed is taken as a measure of radiation exposure. The system was developed using γ radiation from a ^{60}Co source. It was shown that the measured dose was independent of the cell diameter [227]. A Fricke dosimeter was used as the reference of the absorbed dose. The dose actually absorbed by the gas was calculated by the Bragg-Gray principle. The results obtained indicated that there is no significant dependence on the G-factor for N_2 on the cell diameter. The mean $G(\text{N}_2)$ of 11.4 ± 0.8 obtained during these experiments compared well with values reported by others.

The N_2O dosimeter was calibrated for 1-MeV electrons by ionization measurements [228]. The G-factors at 297 K (24 °C) and 106.6 kPa (800 mm Hg) were: $G_{\text{N}_2} = 10.0 \pm 0.2$, $G_{\text{O}_2} = 4.0 \pm 0.4$, $G_{\text{NO}} = 3.9 \pm 0.3$, and $G_{-\text{N}_2\text{O}} = 12.0 \pm 0.4$. All yields increased with increasing temperature. The ratio $G_{\text{NO}} : G_{\text{O}_2}$ increased from 1.0 at 297 K (24 °C) and 106.6 kPa (800 mm Hg) to greater than 2.0 above 423 K (150 °C). The pressure dependence for G_{N_2} and G_{NO} was consistent either with ultimate dissociative electron capture of all electrons and bimolecular deactivation of N_2O^* or with no significant electron capture and termolecular deactivation.

4.7 Decomposition of Nitrous Oxide in Electrical Discharges

4.7.1 Decomposition of Nitrous Oxide in a Corona Discharge

It has been attempted to remove N_2O from industrial waste gases by passing it through a corona discharge at high electric potentials. N_2O becomes easily ionized under those conditions and decomposes, sometimes forming ozone in the process. If ionized N_2O is passed over a catalyst, it may be possible to start the exothermic decomposition of N_2O in a monopropellant rocket without having to preheat the catalyst.

Measurements of the spatial growth of prebreakdown ionization currents in uniform electric fields in mixtures of nitrous oxide and oxygen showed that the ratio of effective primary ionization coefficient to the total gas number density decreased as the oxygen concentration in the mixture increased up to about 10% [229]. Measurements of the breakdown voltage of mixtures with oxygen concentrations up to about 10% showed that the dielectric strength of the mixtures increased above that of N_2O alone.

4.7.2 Decomposition of Nitrous Oxide in a Glow Discharge

The decomposition of nitrous oxide in a glow discharge would be of interest as a means of removal of nitrous oxide as a pollutant in stack gases or as the process taking place at the inlet of a mass spectrometer. It would also take place in the high atmosphere in an aurora.

A time-of-flight mass spectrometer has been used to examine the dissociation of nitrous oxide in a glow discharge, where the dissociation arose from direct electron impact reactions [230]:

and

The overall dissociation coefficient was $7.3 \times 10^{-17} \text{ cm}^2$ for 2.2 Torr N_2O ($E/p \sim 30 \text{ V cm}^{-1} \text{ Torr}^{-1}$) and increased by nearly an order of magnitude when the N_2O was mixed with argon. The discharge product NO altered the discharge conditions significantly and itself became considerably dissociated.

4.7.3 Decomposition of Nitrous Oxide in an Accelerated Electron Beam

Low-energy electron bombardment has been used to disaggregate N_2O clusters. Stronger energy beams will not only disaggregate the clusters but also decompose the N_2O molecule. Ozone and several oxides of nitrogen (NO_2 , N_2O_2 , N_2O_3 , N_2O_4 , and N_2O_5) were observed during the 1-keV electron beam irradiation of a solid N_2O ice sample formed at 25 K [231]. Such reactions may have important implications for the ice chemistry of outer solar system planets/satellites and interstellar ices. Electron

bombardment of nitrous oxide molecular beams can be used as a diagnostic tool to determine the degree of association of N_2O clusters.

The dissociation of N_2O into neutral metastable fragments by electron impact has been investigated for incident electron energies from threshold to 120 eV [232]. A number of dissociation channels that produced $\text{N}_2(^1\Pi_g)$ and $\text{O}(^5\text{S})$ metastable fragments were found. The kinetic energy spectra and excitation functions for both of these metastable species supported a mechanism for the production of $\text{N}_2(^1\Pi_g)$. It was noted that the relatively high kinetic energies of metastable intermediates produced in dissociative excitation may contribute to the heating of the upper atmosphere, particularly under auroral conditions.

Calculated and measured elastic and absorption cross sections using a crossed electron-beam/molecular-beam with electron beams in the intermediate energy range were compared, and the angular distribution of the scattered electrons was converted to absolute cross sections using a relative-flow technique, which showed good agreement between the measured results and theoretical calculations [233]; see also [234–237].

4.7.4 Decomposition of Nitrous Oxide in a Microwave Plasma

The decomposition of nitrous oxide in an electrodeless microwave plasma discharge reactor was examined as a method for the removal of nitrous oxide pollutants from industrial stack gases.

The decomposition of N_2O into N_2 , O_2 , and NO by an electrodeless microwave discharge in $\text{N}_2\text{O}/\text{He}$ or $\text{N}_2\text{O}/\text{Ar}$ mixtures was studied at various total pressures [238–241]. Although discharge could be maintained only in the low total-pressure range of 0.13–10 kPa (1–80 mm Hg) in $\text{N}_2\text{O}/\text{He}$ mixtures at N_2O and He flow rates of 25 and 2000 standard cm^3/min , respectively, stable microwave discharge could be maintained in the wider total-pressure range of 0.13–101 kPa (1–760 mm Hg) in $\text{N}_2\text{O}/\text{Ar}$ mixtures at N_2O and Ar flow rates of 25 and 1000 sccm, respectively, at a microwave power of 200 W. The decomposition efficiency of N_2O in $\text{N}_2\text{O}/\text{Ar}$ mixtures at 101 kPa (760 mm Hg) was measured as a function of the microwave power or the N_2O flow ratio at a relatively high N_2O concentration range of 9900–47600 ppm. Mass spectrometric and optical emission spectroscopic analysis helped to develop a hypothesis for the decomposition mechanism of N_2O under these conditions.

The operating pressure regime of microwave plasma discharges could be expanded by incorporation of microwave absorbers in the reactor. The decomposition of N_2O has been studied in a microwave-absorbent assisted discharge of N_2 at atmospheric pressure [242]. Although a discharge could not be maintained without using microwave absorbents, stable discharge could be maintained by using two types of rods of Zr or W microwave absorbents. The maximum conversion of N_2O was $\geq 97\%$ at a microwave power of 150–200 W and a distance of 10 mm between the rods.

4.8 Nitrous Oxide GDL, CW, and Chemical Lasers

A gas dynamic laser (GDL) is a laser based on differences in relaxation velocities of molecular vibrational states where the lasing medium gas has such properties that an energetically lower vibrational state relaxes faster than a higher vibrational state, and so a population inversion is achieved during expansion. Instead of CO_2 in a mixture with nitrogen or helium, N_2O can be used as the lasing medium [243].

Pulsed coherent emission was obtained from N_2O molecules in a $\text{N}_2\text{O} + \text{He} + \text{N}_2$ supersonic heated mixture emerging from a planar nozzle in a shock tube. The power and duration of the output pulses were a function of the concentration of N_2O , temperature, and pressure [244].

A tunable-diode laser operating in the $2120\text{--}2350\text{ cm}^{-1}$ wavenumber region was used to probe a conventional CW N_2O laser discharge [245]. Absorption lines in more than ten different vibrational bands were observed, enabling one to determine vibrational populations in all levels of concern to the dynamics of the $10\text{-}\mu\text{m}$ N_2O laser. The populations in the three normal modes of vibration of N_2O were found to follow Boltzmann distributions, with the ν_1 and ν_2 modes maintaining a common vibrational temperature under all discharge conditions. The factors limiting the small-signal $10\text{-}\mu\text{m}$ gain were investigated in detail, and it was found that electron deexcitation of the $00(0)1$ level is much more important than N_2O dissociation.

Similar to continuous wave (CW) CO_2 lasers, N_2O can also be used as a lasing medium in electrical discharge lasers. In addition, the exothermic decomposition of nitrous oxide of the reaction of N_2O and CO in a lasing cavity provides sufficient energy to use this as the propellant for a chemical laser.

A pulsed N_2O electron-beam-controlled laser with an optical cavity volume of $\sim 2\text{ L}$ was developed with a radiation energy of 8 J , specific output energy of $16\text{ J L}^{-1}\text{ atm}^{-1}$, and 9% efficiency, which was substantially higher than the performance values known for electric-discharge N_2O lasers [246–248]. The addition of CO to an $\text{N}_2\text{O}/\text{N}_2/\text{He}$ active mixture (or complete substitution of N_2 by CO) improved the energy characteristics of an electron-beam-controlled N_2O laser by more than an order of magnitude.

A simplified two-temperature model was developed for the vibrational energy levels of N_2O and N_2 molecules of an $\text{N}_2\text{O}\text{--}\text{N}_2\text{--He}$ GDL, and the governing equations for the unsteady flow of the gas mixture in a convergent-divergent contour nozzle were solved using a time-dependent numerical technique [249]. Final steady-state distributions were obtained for vibrational temperatures, population inversion, and the small-signal laser gain along the nozzle. It was demonstrated that for plenum temperatures lower than 1200 K , an N_2O GDL is more efficient than a CO_2 GDL under identical operating conditions.

In an effort to optimize the active mixture composition by varying the ratio of molecular (N_2 , CO) and monatomic (He , Ar , Xe) gases to N_2O on the energy characteristics of a pulsed electron-beam-controlled N_2O laser in a device having an optical

volume of ~ 10 L at a gas pressure of 0.25 atm, it was found that the laser output energies were ~ 80 J (a specific output energy of $\sim 30 \text{ J L}^{-1} \text{ atm}^{-1}$) for an active medium temperature $T = 20^\circ\text{C}$, and 106 J ($36 \text{ J L}^{-1} \text{ amagat}^{-1}$) for $T \approx -30^\circ\text{C}$ ($N = 0.3 \text{ amagat}$) [250]. An overall efficiency of $\sim 10\%$ was achieved.

In continuation of this development, an experimental and theoretical investigation was made of the small-signal gain in a pulsed electron-beam-controlled N_2O laser [251]. The gain was found to exceed $\sim 1 \text{ m}^{-1}$. A comparison of the experimental and calculated gain values was used as the basis for estimating the pumping efficiency of N_2O molecules in an electron-beam-controlled discharge and the relaxation constant of the upper active level. The lasing frequency of the N_2O laser was tunable in spectral ranges corresponding to vibrational-rotational transitions from R(46) to R(2) and from P(2) to P(46). The laser output energy, at its maximum in the distribution over the rotational numbers, was ~ 8 J.

4.9 Catalytic Decomposition of Nitrous Oxide

The catalytic decomposition of nitrous oxide is of substantial interest not only for its use as a rocket propellant but also for the abatement of nitrous oxide as a pollutant from combustion processes, industrial processes, and decomposition of organic matter in swamps.

It was decided to deal with the catalytic decomposition of nitrous oxide in *Encyclopedia of Monopropellants*, the chapter Nitrous Oxide Monopropellants. The homogeneous gas phase decomposition of nitrous oxide became a subsection to that chapter since we did not want to separate the two modes of decomposition.

Therefore, the chapter on catalytic decomposition of nitrous oxide was allowed to remain in *Encyclopedia of Monopropellants*. The current section contains all the other physical, chemical, and handling properties of nitrous oxide. The actual design of reactors for decomposing nitrous oxide for use in rocket engines will be discussed in *Encyclopedia of Monopropellants*, where it belongs.

4.10 Combustion Sustained by Nitrous Oxide as an Oxidizer

All publications dealing with combustion of solid fuels with nitrous oxide as an oxidizer may eventually be discussed in a planned future volume on hybrid propellants. All publications dealing with diffusion-flame combustion of gaseous or liquid fuels with nitrous oxide as an oxidizer will be discussed in a future volume on non-hypergolic bipropellants. Premixed mixtures of nitrous oxide with fuels, either in the liquid or gaseous state, usually intended to be used as monopropellants, are discussed in *Encyclopedia of Monopropellants*, following the use of pure nitrous oxide by itself as a monopropellant.

5 Toxicity of Nitrous Oxide

The main concern about the inadvertent inhalation of nitrous oxide is the narcotic effect that may render the accident victim unconscious. Nitrous oxide is heavier than air and may accumulate on the floor of a room.

Even if the inhalation hazard is under control, spills of liquid nitrous oxide leaking from an apparatus and spilled on unprotected skin can cause severe frost damage [252]. Exposure of the skin to nitrous oxide, a liquefied gas stored under pressure in a cylinder, can occur in anesthesiologists and in those involved in recreational misuse of the gas. A case was reported of a man who presented to the emergency department with frostbite on the face after sniffing nitrous oxide. Because of the numbness induced by the anesthetic, the victims do not feel the cold pain that would normally be a warning.

5.1 Inhalation Toxicity of Nitrous Oxide

Nitrous oxide acts as an analgesic at concentrations above 20 vol-% and as an anesthetic at concentrations above 70 vol-% in air. Because of the widespread use of nitrous oxide as an analgesic and anesthetic, the potential side effects of nitrous oxide inhalation have been thoroughly investigated. This affects not only patients that are exposed to this gas rarely in their lifetime but also operating room personnel who may breathe air that has been exhaled by patients undergoing medical treatment. See also Reference [253].

Nitrous oxide concentrations typically used for anesthetic purposes have cardiodepressive effects and can induce cardiac dysrhythmia.

The inhalation toxicity of nitrous oxide is described in the *Material Safety Data Sheet* of a nitrous oxide supplier as follows [254] (quoted verbatim):

Simple asphyxiant. May cause suffocation by displacing the oxygen in the air. Exposure to oxygen-deficient atmosphere (<19.5%) may cause dizziness, drowsiness, nausea, vomiting, excess salivation, diminished mental alertness, loss of consciousness and death. Exposure to atmospheres containing 8–10% or less oxygen will bring about unconsciousness without warning and so quickly that the individuals cannot help or protect themselves. Lack of sufficient oxygen may cause serious injury or death. Anesthetic effects may occur when mixed with oxygen at a ratio of 80% nitrous oxide to 20% oxygen. Laughter effects seem to occur after incipient asphyxia accompanied by the sudden return of oxygen. Nitrous oxide is a slight narcotic. Intentional misuse by deliberately concentrating and inhaling nitrous oxide may be harmful or fatal.

5.2 Toxic Action Mechanisms of Nitrous Oxide

The embryotoxic, teratogenic, neurologic, and hematotoxic activity of nitrous oxide is caused by irreversible oxidation of vitamin B₁₂. The lack of vitamin B₁₂ inhibits me-

thionine synthase, resulting in reduced deoxyribonucleic acid (DNA) synthesis and causes the myelotoxic, neurotoxic, and potentially reproductive toxic effects of N₂O [255, 256].

Neurological impairment from nitrous oxide exposure has been reported at concentrations of several hundred to several thousand ppm; however, decrements in human cognitive and psychomotor functions have been reported at much lower concentrations [257], also tremor [258]. Dentists exposed to nitrous oxide longer than 3000 h within the prior 10 years exhibited neurologic symptoms such as weakness, tingling, and numbness.

A neurological disorder developed after prolonged exposure to nitrous oxide in 15 patients, all but one of whom were dentists [259]. Thirteen patients had abused nitrous oxide to some extent for periods ranging from 3 months to several years, but two patients were exposed to nitrous oxide only professionally, by working in poorly ventilated surgeries. Symptoms included early sensory complaints, loss of balance, leg weakness, gait ataxia, impotence, and sphincter disturbances. Neurological examination showed sensorimotor polyneuropathy, often combined with signs of involvement of the posterior and lateral columns of the spinal cord. The effects can be prevented by folinic acid or methionine supplements in the diet. Nitrous oxide can lead to severe neurological deficits in patients with vitamin B₁₂ deficiency. Neurologic degeneration has been observed in vitamin B₁₂-deficient patients after N₂O exposure of only 1.5 to 3.5 h during routine surgery [260]. Nitrous oxide in anesthetic concentrations is teratogenic in rats, but in humans there is no unambiguous epidemiological evidence for an increase of fetal abnormalities following N₂O exposure during pregnancy, typically experienced by female dental assistants in poorly ventilated dentist's offices.

Nitrous oxide interacts with vitamin B₁₂, resulting in selective inhibition of methionine synthase, a key enzyme in methionine and folate metabolism. Thus, nitrous oxide may alter the one-carbon and methyl-group transfer most important for DNA, purine, and thymidylate synthesis. Detailed summaries of the toxicity of N₂O are published in [261–264].

The adoption by the American Conference of Governmental Industrial Hygienists of a Threshold Limit Value (TLV) of 50 ppm for an 8-h average exposure to nitrous oxide was in response to numerous publications in the 1980s that outlined the potential dangers of routinely inhaling N₂O. Although N₂O was for many years believed to have no toxicity other than that associated with its anesthetic action, bone marrow depression in patients administered N₂O for extended periods of time and neurological abnormalities in healthcare workers who inhaled N₂O repeatedly recreationally have disproved this notion. Retrospective surveys of dental and medical personnel have also linked occupational exposure to N₂O with a number of health problems and possible reproductive abnormalities. Nitrous oxide reacts with the reduced form of vitamin B₁₂, thereby inhibiting the action of methionine synthase, an enzyme that indirectly supports methylation reactions and nucleic acid synthesis. Many, if not all, of the non-anesthetic-related adverse effects of N₂O may be based on this reaction.

Animal and human studies indicated that the toxic effects of N_2O are concentration- and time-dependent. It was suggested that a time-weighted average of 100 ppm for an 8-h workday and/or a time-weighted average of 400 ppm per anesthetic administration would provide adequate protection of dental personnel and be achievable with existing pollution control methods [265]. It is difficult to extrapolate from animal tests to human health hazards on nitrous oxide [266].

5.3 Teratogenicity of Nitrous Oxide

In animal tests with pregnant Sprague-Dawley rats and concentrations of 50 vol-% N_2O , even single exposure during days of gestation between 8 and 10 d, the exposure caused malformations in offspring, and N_2O was classified as embryotoxic and teratogenic under those conditions [267–271]. A maximum of fetal deformations was observed in rats exposed on day 9 of the pregnancy, but no effects were observed with 75% N_2O exposure during days 11 to 15 or 16 to 20 of the pregnancy [272]. Concentrations of 35 vol-% or below were not embryo- or fetotoxic [273]. The no-effect level was established at 10 vol-% N_2O . Epidemiological studies of humans exposed to N_2O as operating room personnel have not identified any teratogenicity of N_2O in humans.

On the other hand, some MSDS caution as follows: “Reproductive toxicity has been observed in humans and animals following exposure to nitrous oxide in concentrations in excess of the TLV. Exposure to nitrous oxide alone resulted in a 50% increase in congenital abnormalities and a 100% increase in spontaneous abortion in female dental assistants compared to non-users of nitrous oxide.”

5.4 Fatal Accidents as the Result of Nitrous Oxide Inhalation

There have been numerous reports of fatal accidents due to the recreational substance abuse and inhalation of nitrous oxide to achieve a hallucinogenic “high” [274, 275]. In comparison to those frequent fatalities there are only few fatalities where the exposure was truly an industrial accident.

The abuse of nitrous oxide while on the job caused at least 11 deaths in 1984 to 1987, as found in investigations by the Occupational Safety and Health Administration and in reports to the Consumer Product Safety Commission [276]. The 11 deaths involved recreational inhalation of N_2O by young male employees from cylinders normally used for legitimate business purposes. In six cases, the victims worked in food serving establishments and inhaled N_2O that was used to power whipped cream dispensers. Moreover, there have been fatal errors in nitrous oxide (and lack of oxygen) delivery in the operating room, either by human error or equipment failure [277].

6 Environmental Impact of Nitrous Oxide

It has been estimated that among the greenhouse gases carbon dioxide, methane, and others, the contribution of nitrous oxide to the greenhouse effect is 6%. Depending on which source you believe, the heat-trapping greenhouse-effect power of nitrous oxide is variously reported as anywhere between 260 and 310% of that of carbon dioxide, and its half lifetime in the atmosphere is substantially longer than that of carbon dioxide since there are no known biological sinks for nitrous oxide.

A good summary of the role of nitrous oxide in the global nitrogen cycle is given in [278]. Nitrous oxide is an important trace component of the Earth's atmosphere with a 120-year atmospheric residence time. It exhibits a global warming potential 310 times that of CO_2 on a per molecule basis, and like CO_2 , its atmospheric concentration is increasing. Nitrous oxide is produced naturally as a byproduct of nitrification and denitrification. There are also several anthropogenic sources. The reactions known to yield N_2O must be identified before one can control the N_2O buildup in the atmosphere. Fundamental chemical kinetics and mechanisms that lead to its formation depend on research involving nitric acid, nitric oxide, and ammonium nitrate as N_2O precursors.

There are several books with information about nitrous oxide and climate change [279, 280]. Nitrous oxide is the third most important (in global warming terms) of the greenhouse gases, after carbon dioxide and methane. Although it only comprises only 320 parts per billion of the earth's atmosphere, it has a so-called global warming potential nearly 300 times greater than that of carbon dioxide. N_2O emissions are difficult to estimate because they are predominantly biogenic in origin. N_2O is formed in soils and oceans throughout the world, by the microbial processes of nitrification and denitrification that utilize the reactive nitrogen compounds ammonium and nitrate.

7 Materials' Compatibility with Nitrous Oxide

All materials that may come into contact with nitrous oxide need to be thoroughly cleaned. SpaceDev, the hybrid rocket motor supplier for Scaled Composites and its SpaceShipOne and SpaceShipTwo commercial spacecraft, and its predecessor AMROC have accumulated a vast amount of experience in handling nitrous oxide and selecting materials that are compatible with it [88]. That includes special methods for cleaning all components that come into contact with nitrous oxide prior to each use.

7.1 Metallic Materials of Construction

Stainless steel CRES-304 bomblets with 52 mL internal volume were filled with 25 mL of liquid N_2O and heated to 302.6 K (85 °F), which is just below the critical point for

30 d [202]. As blank reference samples, in addition to the six tests with impurities or metals in contact with N_2O in CRES-304 bomblets, one CRES-304 bomblet and one CRES-316 bomblet (both without any test impurity) were filled with N_2O and placed in the bath under the same test conditions. After 30 days at 302.6 K (85 °F), no pressure buildup was noted in any of the 8 compatibility containers containing Cu, Ni, Fe_2O_3 , Cr_2O_3 , FX 190 3-M Corp. leak test solution or CRES-304 wire mesh screen.

7.2 Non-metallic Materials of Construction

Impact tests of 19 materials immersed in liquid N_2O were conducted at the White Sands Test Facility by NASA in a pressurized test apparatus [281]. These tests consisted of placing 12-mm (1/2-in.) diameter specimens in a cup-like device, immersing the cup and specimen in liquid N_2O , and dropping a 9-kg (20-lb_m) 12-mm (1/2-in.) diameter ballast weight on the specimen. The energy density of the impactor at the area of impact was 762 N/m² (367.5 ft-lb_f/sq. in.). The results showed that there were no effects to the materials and no problems with N_2O ignition. The materials tested included metals, alloys, polymers, and grease.

Three materials were tested in a bladder materials evaluation program [282]. These were FEP Teflon, AF-E-332, and Arrowhead Rubber AP-2962. The tests consisted of immersing the specimens in liquid N_2O at room temperature for several days and then comparing the mechanical properties of specimens. It was found that the tensile properties and resistance to cyclic strain of both FEP Teflon and AF-E-332 were practically unaffected by exposure to liquid N_2O , but the properties of the Arrowhead Rubber degraded considerably. These tests eliminated Arrowhead Rubber as a possible bladder material.

Due to the good solvent properties and high rate of permeation of liquid N_2O , it is important to test polymeric seals intended to be used in N_2O systems for swelling in liquid N_2O .

8 Components for Nitrous Oxide Systems

Ignition of combustible materials will happen more readily in the presence of nitrous oxide. This is why the Department of Transportation (DOT) requires that cylinders containing nitrous oxide, meet the requirements listed in the Code of Federal Regulations (CFR-49) section 173.304 “Charging of cylinders with liquefied compressed gas” paragraph (a)(4)(ii). Each cylinder must be cleaned in compliance with the requirements of Federal Specification RR-C-901c § 3.7.2 and 3.8.2. Cleaning agents equivalent to those specified in RR-C-901c may be used; however, any cleaning agent must not be capable of reacting with oxygen or nitrous oxide [283]. The piped systems for the in-plant transfer and distribution of nitrous oxide shall be designed, installed, maintained,

and operated in accordance with Compressed Gas Association (CGA) Pamphlet G-8.1-1964 [284, 285]; as specified in Section 1910.6.

8.1 On-Site Storage Systems

The design of on-site storage tanks and distribution systems for nitrous oxide is described in [286].

8.2 Design of Self-Pressurizing Feed Systems

Most rockets in launch vehicles feed the propellants by the use of turbopumps, one for the oxidizer and one for the fuel. Satellites and space probes used pressure-fed feed systems where a pressurant gas, usually helium, pressurizes a propellant tank and expels the liquid into the rocket engine. Pressure-fed systems are very similar for bipropellant systems and monopropellant systems or for some hybrid systems. Most propellants that are pressure-fed do not have a very high vapor pressure of their own and depend on the pressurant gas to get moving. Nitrous oxide (and a few other propellants, such as propane) are an exception in this group of propellants in that they have sufficient vapor pressure to expel themselves from a propellant tank without the aid of a pressurant gas like helium. However, the moment liquid is withdrawn from the tank, and some of the liquid has to vaporize to maintain the pressure in the enlarging vapor space, the energy required for vaporization is withdrawn from the liquid and may cause it to freeze if no heat is supplied from the outside and if the fluid has a narrow liquidus range like nitrous oxide or carbon dioxide. This would be the case regardless of whether the nitrous oxide is used as an oxidizer in a bipropellant engine or a hybrid motor or used as a monopropellant.

Accurate modeling of propellant tank pressurization is an essential element of the prediction of rocket performance. A real fluid, quasi-phase-equilibrium thermodynamic propellant tank model that is applicable to a broad range of propellants including those that are highly volatile and/or cryogenic was developed and validated by comparison with the measured results of cold flow blow-down tests or a self-pressurizing nitrous oxide system [287, 288]. Data from one of the cold flow tests showed evidence of stratification within the oxidizer tank during the blowdown. Accurate modeling of the propellant evaporation rate is a crucial element in the prediction of the pressure history of the propellant expulsion process. With a change in the input parameters, this model can also be used for other volatile propellants.

Regardless of whether N_2O is to be used as working fluid for cold gas thrusters, electrothermal thrusters, as monopropellant, or as oxidizer in bipropellant or hybrid propulsion systems, one property that all applications take advantage of is the self-

pressurization of N_2O tanks, expelling liquid N_2O under its own vapor pressure, which eliminates the need for a separate tank pressurization system.

One of the advantages of nitrous oxide over storable propellants that require a helium pressurization system is that below certain propellant withdrawal rates, the tank is self-pressurizing. An instrumented experimental ground test system was built simulating a satellite to study the propellant-tank self-pressurization process of a sub-Newton-thrust-class N_2O monopropellant propulsion system [289]. Numerical simulation using a three-region lumped parameter model was conducted to simulate the same process. Simulation results under adiabatic wall conditions agreed well with the experimental data. Both experimental and simulation results showed that the heat compensation for the propellant tank heat balance is necessary during the propellant self-pressurization propellant withdrawal, in order to keep stability of the tank pressure. The initial filling factor (ullage), the volume of the tank, and the propellant flow rate influence the rate of propellant tank pressure decay; see also Reference [290].

A theoretical model was developed that predicted the pressure draining history of a self-pressurized N_2O oxidizer tank with helium as the pressurant to within $\pm 5\%$ of experiment [291]. Two models were produced, both assuming thermodynamic equilibrium states at every point in time throughout draining. The first model assumed that the P - V - T behavior of the nitrous oxide/helium mixture is ideal; the second model assumed that the mixture adheres to the non-ideal Peng-Robinson equation of state. Results from both models were compared to experimental data from pure nitrous oxide (no helium pressurization) draining tests [287]. The additional complexity introduced by a non-ideal equation of state was necessary due to the high pressures encountered in the tank during draining. It was found that despite the highly non-linear nature of the draining process, the liquid flow rate from the tank remained reasonably constant, which is a highly desirable characteristic of a rocket oxidizer delivery system.

An engineering model was developed to calculate the two-phase saturated fluid mass flow rate of self-pressurizing nitrous oxide [292, 293]. The model assumed adiabatic expansion for which, during propellant discharge from the tank, the current tank fluid entropy and the fluid entropy that has discharged through the feed system equate to the initial, predischARGE entropy of fluid in the tank. While flow of N_2O through a network of tubing cannot be accurately modeled using traditional ideal gas, compressible or incompressible flow assumptions, a more accurate mass flow rate one-dimensional analysis included both incompressible fluid and homogeneous equilibrium mass flow rate models. Mass flow calculations from the two models were independently weighted and summed to obtain a representative two-phase mass flow rate. The model excellently predicted mass flow rates as verified by comparison to experimental cold flow data. The experimental conditions resulting from the test apparatus setup produced fluid stratification and incomplete mixing effects that cannot yet

be modeled by the algorithm as developed. Therefore, the run tank and temperature drops as predicted by the model were significantly larger than measured. The results were compared to those obtained with CO_2 , which behaves very similarly to N_2O .

Hybrid rockets commonly use nitrous oxide as a self-pressurizing oxidizer, but no comprehensive models existed for predicting the performance of such a system. To aid in the development of such a model, an experimental apparatus with a transparent cylinder was designed that allowed for visual observation as well as pressure, temperature, and mass flow rate measurements [294]. Because the physical properties are very similar, carbon dioxide was used as a substitute for nitrous oxide, facilitating laboratory-scale testing. Initial results of tests with this system showed that there is significant boiling within the liquid and that the propellant is not maintained in thermodynamic equilibrium.

A self-pressurizing propellant like nitrous oxide has the potential to reduce propulsion system mass and complexity. In the case of nitrous oxide, the liquid propellant has a high vapor pressure that may be used to pressurize the liquid, allowing a traditional pressurization system to be eliminated entirely or significantly reduced in size. However, the expulsion dynamics of a self-pressurizing propellant tank must be accurately modeled for system performance to be predicted. To aid in the development of such a model, an experimental apparatus has been constructed with a transparent polycarbonate cylinder functioning as a propellant tank [295, 296]. This allowed for optical measurements to be made in addition to traditional pressure, temperature, and mass flow rate measurements. Carbon dioxide has been identified as an analog substitute for nitrous oxide, facilitating a significant reduction in the cost, negative environmental consequences, and hazards to personnel associated with this type of testing. Both the supercharge configuration and the mass flow rate strongly affect the dynamics of self-pressurizing propellants. In order to demonstrate carbon dioxide's validity as an analog ("stand-in") for nitrous oxide, side-by-side comparison tests with nitrous oxide and carbon dioxide have also been performed.

Subsequently, an improved system was constructed [297]. Several pressure transducers were added to record pressure in the ullage, at the base of the tank, and in the exit lines. Temperature sensors in these locations allowed the complete determination of the thermodynamic state. Fast response time thermocouples have been used to capture transient temperature changes. Significant amounts of boiling and condensation were observed, and transient bubble phenomena appeared to be responsible for some characteristics of the pressure history. By using a pressure vessel manufactured from cast acrylic as opposed to the previous extruded polycarbonate, the optical clarity has been greatly increased.

8.3 Propellant Tanks for Nitrous Oxide

The design of a lightweight pressurized oxidizer tank for a hybrid sounding rocket with a capacity of 20 kg of either nitrous oxide or hydrogen peroxide envisioned a tank made from graphite epoxy prepreg composite with unidirectional lamina designed for a burst pressure of 13 MPa (2000 psi) and had the shape of a cylinder with hemispherical ends [298]. The tank diameter would be 20.3 cm (8 in.), and the total length would be 1.52 m (5 ft.) This gave a total dry mass of 3.7 kg.

9 Safety Properties of Nitrous Oxide

The guidelines issued by Compressed Gas Association provide a reliable summary of precautions for the safe handling of nitrous oxide [299]. As part of the proposed use of N_2O as an oxidizer in a combustion process for an airborne laser weapon system, a number of potential problem areas were investigated by Air Force Weapons Laboratory (AFWL) or by other organizations under contract to AFWL [92]. Two of the programs investigated the decomposition characteristics of N_2O/CO mixtures. It was determined that the decomposition of gaseous N_2O is not difficult to initiate, but that it is also easily quenched. Tests with the N_2O/CO mixture revealed that this combination has significant explosive potential; however, it was difficult to initiate such an explosion. Another series of investigations addressed potential flow choking problems. The liquid N_2O in the system is pressurized by helium in the ullage of the tank and absorbed some of this He. With more than about 0.5 mol-% absorbed He, the effective throat area of a cavitating venturi used in the metering system was appreciably reduced. A second aspect of the flow studies concerned the possibility of N_2O solidification when it had to be dumped overboard under emergency airborne conditions. Tests confirmed the formation of N_2O snow when liquid N_2O was dumped into a vacuum chamber; however, no flow problems were encountered.

Additional information on the safe handling of nitrous oxide is provided in the Material Safety Data Sheets available from nitrous oxide manufacturers and distributors, for instance:

Refrigerated Liquid:

http://msds.lindeus.com/files/msds/WPS_LIND_067_NA_MSDS_FINAL_REV_9_2_10.pdf

Compressed Gas: [254]. Section 10. STABILITY AND REACTIVITY in the latter MSDS describes N_2O gas as “**Stability: Stable**”, a misleading description that we question, but a few lines down the MSDS is more specific:

Hazardous Decomposition Products

At elevated temperatures, nitrous oxide decomposes into nitrogen and oxygen, the rate of decomposition being appreciable at about 1112°F (600 °C). Nitrous oxide exposed to fire or other intense heat source may decompose violently.

The recommended maximum storage temperature for compressed gas cylinders filled with N_2O gas is 225 K ($52^\circ\text{C} = 125^\circ\text{F}$).

During an investigation of potentially catastrophic explosions propagated in condensed-phase nitric oxide NO (not N_2O) at temperatures near its normal boiling point, a control experiment, made in the same way using liquid N_2O instead of liquid NO at 85 K, showed no evidence of oxidation or explosion [300]. These explosion experiments were in a vertical CRES-304 stainless steel pipe, 52 mm internal diameter (I.D.), 4 mm wall thickness, and 1220 mm length. All samples were initiated by the detonation of an RDX booster charge.

A very thorough study of the explosion potential of nitrous oxide was conducted by several contractors under sponsorship of the US Air Force [202]. The test program was divided into three phases: **(1)** ignitability of gaseous N_2O , **(2)** ignitability of liquid N_2O , and **(3)** materials' compatibility of liquid N_2O . The results are discussed in other sections of this book.

The conditions under which the decomposition of gaseous nitrous oxide proceeds with explosive force were determined in closed vessels at room temperature and at initial pressures between 0.05 and 8 bar and with various methods of initiation [301]. The pressure profile in the vessels was measured, and, in some cases, the reaction was filmed with a high-speed camera in a windowed bomb. The decomposition products were analyzed by GC. In the high-pressure regime, the ratio of explosion pressure to initial pressure increased with increasing initial pressure. The rate of decomposition was relatively slow, and the type and location of the ignition source and the geometry and the size of the closed bomb had a substantial influence on the rate of reaction and the degree of N_2O decomposition. It was found that at least 30 vol.-% of a diluent gas (air, oxygen or nitrogen) was required to prevent an explosive decomposition. For a container containing both liquid and gaseous N_2O , the vapor phase was no longer detonable after the vapor pressure dropped to below 5.7 bar, which corresponds to a liquid temperature of 218.1 K (-55°C).

Besides avoiding all potential sources of ignition, there are other steps the designer can take to prevent or mitigate explosion hazards when operating at high pressures with gases capable of explosive decomposition such as nitrous oxide or acetylene [302].

In the wake of the accident at Scaled Composites at Mojave in August 2007, a thorough literature search and critical evaluation of available hazard property data for nitrous oxide was conducted [303]. Accounts of serious, large N_2O system accidents are mysterious since a technically satisfying explanation of how the incidents occurred seems lacking. The inadequacy of technical information for serious N_2O incidents indicated that safety practice understanding beyond current knowledge is needed. At a minimum, application of some standard safety practices used with high-pressure oxygen systems, but not specified for N_2O operations, may provide some safety improvements. The inadequacy of historical N_2O hazard study experiments was that they used too small volumes in their studies, and scaling criteria were ne-

glected. N_2O /organic material mixtures constitute special hazards. One of the several potential sources of ignition in any flowing, non-conductive fluid is the buildup of electrostatic charges and an electrostatic discharge spark ignition. The triboelectric effect is the generation of electrostatic charges when differing materials are separated or rubbed or flow over one another. With highly insulating materials and large surface areas, voltages can become quite large. Highly insulating materials might be those having an electrical resistance above $10^{10} \Omega/\text{cm}$. For instance, solid propellants having electric resistances above $10^{10} \Omega/\text{cm}$ can be sensitive to electrostatic ignitions, while solid propellants having electrical resistance below $10^{10} \Omega/\text{cm}$ are insensitive to fire ignition by ESD sparks. Solid propellants are often coated with graphite powder to make them conductive. Nitrous oxide is a material that has very high electrical resistance in both gas and liquid states. For comparison, as gas pressure is increased, ignition energies for initiation of fire with solid propellants can diminish dramatically. Threshold electrostatic discharge voltage for getting a solid propellant ignition between 1 atmosphere (0.10 MPa, 14.7 psi) and 40 atmospheres (4.1 MPa, 600 psi) can decrease by a factor of 30. Since the spark energy is proportional to voltage squared, the spark energy for propellant ignition at 40 atmosphere pressure was about one-thousandth $= (1/30)^2$ of that required for propellant ignition at 1 atmosphere pressure. Since N_2O vapor pressure at 293 K (20 °C) is about 5.2 MPa (50 atm = 750 psi), pressure conditions are fairly optimal for having ESD events occurring that might attain combustion ignitions with N_2O /fuel mixtures. The fuel in this instant might be gasket materials, lubricant contamination, or the composite fiber-reinforced tank wall.

A very thorough evaluation of hazards in using nitrous oxide as an oxidizer in hybrid propulsion systems and other industrial applications has been conducted with a model of N_2O decomposition events [58]. In order to underscore the importance of such calculations, that paper contains a list of nitrous oxide decomposition accidents compiled from literature sources. Consequently, the hazard analysis looked at three hazard scenarios in a rocket: **(1)** N_2O decomposition in the oxidizer tank, **(2)** N_2O decomposition in the feed system, and **(3)** uncontrolled decomposition in the combustion chamber. The primary objective of this paper was to evaluate and assess the hazards that exist in N_2O -based propulsion systems by using the fundamental understanding of the N_2O decomposition physics/chemistry. A secondary goal was to establish a list of practical recommendations for the safe use of nitrous oxide. The decomposition of nitrous oxide was also compared to that of another monopropellant, hydrogen peroxide. The reaction rate constant for H_2O_2 is almost six orders of magnitude larger than the rate constant for N_2O decomposition. Approximately half of this difference is attributed to the lower value of the reaction rate coefficient r_A (primarily due to the spin forbidden transition of N_2O), and the other half is due to the lower activation energy associated with the decomposition of H_2O_2 (203 kJ/mol = 48.5 kcal/mol versus 243 kJ/mol = 58 kcal/mol for N_2O).

Safety precautions recommended for use of nitrous oxide in hybrid rockets apply just as well to all other rocket uses of nitrous oxide [88].

9.1 Autoignition Temperature of Gaseous Nitrous Oxide

The temperature above which the decomposition of gaseous nitrous oxide becomes self-sustaining and potentially leads to explosions depends on the pressure of the gas, the dimensions of the reaction vessel, and the materials of the hot surfaces that the gas is in contact with.

The autoignition of gaseous nitrous oxide was already discussed in the chapter on thermal stability and decomposition of nitrous oxide, see Section 4.4.

Nitrous oxide ignited spontaneously during attempts to fill a heated high-pressure detonation tube to an initial pressure of 2.16 MPa (21.4 atm). The tube was at a temperature of 598 K (325 °C) [304]. The ignition of nitrous oxide flowing at 0.05 m/s over a heated 3-mm diameter metal rod was dependent on the chamber pressure and flow rate. Ignition was only possible at pressures above 0.3 MPa. The temperatures of ignition decreased with increasing pressure, as shown in Table 23. The rod was heated up at a rate of 25–30 K/s.

Table 23: Ignition temperature of nitrous oxide gas.

N ₂ O pressure, MPa	Ignition temperature, K	
	Flowing gas	Natural convection gas
0.3	1515 ± 15	
0.4	1473 ± 20	
0.5	1454 ± 10	
0.6	1406 ± 10	
0.7	1398 ± 15	
1.1	1359 ± 10	1308 ± 15
2.1	1309 ± 10	1278 ± 15
3.1	1292 ± 10	1273 ± 10
4.1	1280 ± 15	1238 ± 20

Data source: [304]

9.1.1 Ignitability and Detonability of Gaseous Nitrous Oxide

The detonability of gaseous nitrous oxide was investigated at initial temperatures from 296 to 483 K (23 to 210 °C = 533 to 870 R) and at initial pressures from 2.16 to 20.92 MPa (21.4 to 207.1 atm) in a high-pressure detonation tube (32 mm I. D. × 1.14 m = 1.25 in. I. D. × 45 in. in length) [304]. Ignition was provided by a pyrofuse Al/Pd alloy wire rapidly heated with a 24-V DC power supply. No true detonations developed during any of these experiments. At first, experiments were conducted with the gas initially at room temperature, while the initial pressures ranged from 3.53 to 6.28 MPa (35.0 to 62.2 atm). The maximum pressure observed at the tube end was only 1.15 to 1.64 times the initial pressure, whereas a detonation wave would have produced an impact pressure 25 times higher than the initial pressure. Some explosions,

however, were encountered. The maximum impact pressure was 3.66 times greater than the initial pressure as measured by a quartz crystal transducer. The time intervals of the reactions (from ignition to the maximum pressures) lasted from 1 to 4 s, which indicated that relatively slow reactions occurred. The results showed that nitrous oxide will decompose and burn deflagratively under the conditions employed. At certain higher initial pressures and temperatures, some explosions occurred.

Explosion and decomposition limits of gaseous nitrous oxide with and without diluent gases have been determined in a 117-mL cylindrical reaction chamber for pure nitrous oxide and mixtures consisting of (volume parts) $1\text{N}_2\text{O} + 0.25\text{air}$, $1\text{N}_2\text{O} + 0.88\text{N}_2$, and $1\text{N}_2\text{O} + 0.88\text{N}_2 + 0.50\text{air}$ in order to minimize the explosion risk if using such gas mixtures for aerodynamic tests in supersonic wind tunnels [203]. Two types of igniters were employed: (1) a 0.127-mm (0.005-in.) diameter copper wire was melted by applying 31 V DC to its terminals and (2) a 0.5-mm (0.020-in.) diameter platinum glow wire was heated with approximately 210 W AC. The explosion limit curve for nitrous oxide followed an exponential path for both igniters. Explosions could not be produced in the $\text{N}_2\text{O} + 0.25\text{air}$ mixture. However, slow reactions were observed when the mixture was preheated to between 593 and 887 K. No reactions could be initiated in the $1\text{N}_2\text{O} + 0.88\text{N}_2$ and $1\text{N}_2\text{O} + 0.88\text{N}_2 + 0.50\text{air}$ mixtures. Experiments with nitrous oxide were conducted at initial temperatures of 296, 348, 373, 423, 473, 523, 573, and 623 K with initial pressures ranging from 0.1 to 4.85 MPa (2 to 48 atm). The electric current melted the copper wire very quickly, thereby producing a concentrated heat source for ignition. The initial experiments were carried out at low pressures (2 atm) and at ambient temperature (296 K). In later experiments the temperature was maintained constant, while the pressure was elevated gradually from experiment to experiment until an explosion was obtained. For a given initial temperature, measurements were made up to pressures well within the explosion region to make sure that the explosion limit had actually been reached and exceeded. Then, the temperature was elevated, and the experiments were repeated. This procedure was continued up to a temperature of 623 K, which was the maximum temperature obtainable with the experimental equipment at that time. At 623 K, the explosion limit was at 0.2 MPa (2 atm). Although the explosion limit in Figure 44 was drawn as a sharp line, it is more likely a band of a given thickness. For the data in Figure 44, ignition was achieved by melting a 0.127-mm (0.005-in.) diameter copper wire with 31 V.

Similarly, in a second series of tests, the explosion limits of pure nitrous oxide ignited by a platinum glow wire were determined at various temperatures between 423 and 1035 K. In this temperature interval, a pressure range from 0.1 to 7.57 MPa (2–75 atm) was investigated. Experiments were performed in a heavy-walled stainless steel cylindrical reaction vessel. The volume of the reaction vessel was 117 mL. The graphic representation of the explosion boundary was not as clean as the one with

Figure 44: Explosion limits of gaseous nitrous oxide. (Reproduced and modified from [203].)

the exploding copper wire shown in Figure 44. There was a transition regime where only very slow and only partial decomposition was observed. The decomposition time, as obtained from pressure-time traces, was of the order of 0.2 to 0.4 s, which is very slow. After the reaction products had cooled off, the final pressure of the closed vessel exceeded the starting pressure by 30–45%. Dilution of nitrous oxide with helium retarded the spark ignition in a 15-cm (6-in.) diameter pipe under most of the conditions summarized in Table 24.

Table 24: Test conditions for spark ignition of gaseous N₂O/He mixtures.

Mol fraction N ₂ O	Mix total pressure		Pre-test temperature		Comments
MPa	psia	K	°F		
0.33	14.45	2100	297	75	No temperature or pressure rise
0.47	15.14	2200	297	75	No temperature or pressure rise
0.49	9.63	1400	296	74	No temperature or pressure rise
0.5	10.32	1500	300	80	No temperature or pressure rise
0.63	7.57	1100	296	74	No temperature or pressure rise
0.84	5.50	800	296	73	No temperature or pressure rise
0.93	4.75	690	294	70	Mixture ignited; chamber ruptured; flame propagation rate: 40 cm/s

Data source: [92]

Figure 9 on page 20 of an accident investigation report shows a graph of critical diameters of tubing for the propagation of nitrous oxide decomposition as a function of temperature and pressure [305]. It was not shown how the authors arrived at this illustration; see also [306, 307].

9.2 Shock Sensitivity and Detonability of Liquid Nitrous Oxide

Ignition and detonation tests of liquid N_2O were conducted in a steel pipe with a diameter of 50 mm (2in.) and length of 30 cm (12in.) [202]. To conduct a test, the pipe was cold-filled with liquid N_2O and warmed to the desired temperature. Two sets of ignition tests were conducted: electrical resistance heated wire ignition tests and explosive cap ignition tests. Only slight pressure and temperature increases were recorded when the electrical igniter was fired. The tests showed that any N_2O that may be vaporized and ignited by the exploding wire was immediately quenched by the surrounding liquid. The explosive cap ignition tests were essentially the same as the electrical ignition tests, except that the exploding wire was replaced with a standard No. 6 blasting cap. In all, eight tests were conducted, four using just plain water to provide a basis of pure hydraulic shock for comparison and four using liquid N_2O . Of the four tests using liquid N_2O , one bulged the tube slightly as in the first three water tests, and the other three ruptured the tubes. The three ruptured tubes were permanently stretched about 20% before rupture. If the liquid N_2O had fully detonated, the energy released would have been equivalent to almost 1 kg (2lb) of TNT. This quantity of detonating TNT would have broken the pipe into many small pieces of shrapnel. The difference in results between the N_2O tests and the water tests clearly showed that some N_2O decomposition occurred. The relatively small amount of damage, however, also showed that the reaction is either slow or quenched.

Using the same techniques as previously developed for detonability testing of nitric oxide (which was much more sensitive than nitrous oxide) the detonation characteristics of nitrous oxide as a solid and non-boiling liquid were examined at USBM [308]. Solid N_2O (136 K, 0.1 MPa) and non-boiling liquid N_2O (197 K, 0.4 MPa) confined in a 26.6-mm-ID by 3.38-mm-wall Schedule 40 steel pipe failed to initiate and detonate when shocked with a 50-g tetryl donor charge close-coupled to a 1.27-mm-thick steel attenuator foil that sealed the bottom of the container [309].

In one of the first systematic studies of nitrous oxide ignition by a local heat source leading to explosions in the gas phase the pressure had to be at least 1.6 atm [206]. Since nitrous oxide is used in practice at elevated pressures, the classification of nitrous oxide as a non-explosive gas based on atmospheric-pressure tests seems incorrect. In estimating the explosion hazard of nitrous oxide two important circumstances must be considered: its sensitivity to the presence of combustible contaminants (since it is an efficient oxidizer) and a sufficiently high temperature (309 K) in a liquid-filled tank with ullage space to raise the vapor pressure into the detonable regime.

9.3 Detonability of Nitrous Oxide/Fuel Mixtures

The detonability of nitrous oxide is enhanced, and it becomes more sensitive in the presence of combustibles, even trace amounts of combustibles like oil. On the other hand, mixtures of nitrous oxide with a wide range of fuels have been studied as monopropellants because nitrous oxide/fuel mixtures would give a higher Isp than nitrous oxide by itself. These premixed monopropellant mixtures will be discussed in *Encyclopedia of Monopropellants*. The detonability of liquid nitrous oxide/ethylene mixtures was investigated extensively. These mixtures have been evaluated as monopropellants.

The detonability of liquid nitrous oxide was tested as part of a program that primarily investigated the detonability of liquid nitrous oxide/carbon monoxide mixtures that were considered as a laser propellant [92]. In those experiments, the blast hazards of $\text{N}_2\text{O}/\text{CO}$ mixtures were examined by firing detonators in liquid $\text{N}_2\text{O}/\text{CO}$ mixtures, which were held in cylindrical containers with a diameter of 90 cm (3 ft.). The total liquid depth was approximately 30 cm (1 ft.), and explosion of the stoichiometric liquid mixture was attempted by means of either two blasting caps or a blasting cap and a squib. The results of six tests showed that while fires occurred in all cases, explosions only occurred in two cases, and both of these used dual blasting caps for ignition. A limited test program was conducted to obtain preliminary explosive yield data for the propellant combination of liquid carbon monoxide and liquid nitrous oxide, under conditions that simulate credible failure modes in a planned test facility [310]. During the course of the program ten tests were conducted using mixtures of these propellants in both liquid and gas phases. Propellant weights ranged from about 50 to 800 lbs. The results from the tests showed that the propellant combination has significant explosive potential, but that it is much more difficult to initiate an explosion in this combination than in the other liquid propellant combinations studied previously.

9.3.1 Adiabatic Compression Sensitivity of Nitrous Oxide

Adiabatic compression of N_2O gas into 51-mm (2-in.) tubes at about 283 K ($10^\circ\text{C} = 50^\circ\text{F}$) temperature would not start monopropellant decomposition at compression rates of 4.1 MPa/s (600 psi/s), but monopropellant decomposition would occur at higher gas compression rates near 6.9 MPa/s (1000 psi/s) [202]. In the 51-mm tubes, N_2O monopropellant decomposition was observed to quench as added cool N_2O gas was admitted to the reaction vessel. Decomposition reaction quenching was expected to be less likely as the container being pressurized became larger in diameter. The threshold adiabatic compression rate to initiate N_2O decomposition at 293 K (20°C) would be expected to attain a fixed minimum value once some critical vessel diameter was exceeded. That critical vessel diameter is unknown, but the diameter is likely to exceed the 51 mm diameter (2 in.) that was used during testing. The threshold minimum pressurization rate at 293 K (20°C) in a larger diameter would likely fall to a value less than the 6.9 MPa

(1000 psi/s) observed at the 51 mm (2 inch) diameter employed during these adiabatic compression tests [311].

Cavitation involves the rapid formation and collapse of vapor bubbles in flowing liquids. Cavitation in turbopumps and in propellant feed systems must be avoided if the fluid is potentially detonable, like nitrous oxide. A computer simulation of the liquid phase flow of nitrous oxide under high pressure was used to predict and avoid the cavitation in the feed system lines of rocket engines [312]. The method involved a substantially simplified 1-D description of the fluid motion with sufficiently accurate determination of cavitation risk where the feeding duct exhibits blunt variations of the cross area or steep turns and corners involving sensible static pressure variations of the fluid.

9.3.2 Boiling Liquid Expanding Vapor Explosion (BLEVE) of Liquid Nitrous Oxide

Even without a chemical reaction leading to the decomposition of nitrous oxide, the rupture of a pressurized tank containing liquid N_2O can cause substantial damage. Similar explosions can occur with more inert cryogenic liquids or condensed liquids under their own vapor pressure at room temperature such as CO_2 or LPG. These types of physical explosions are called **Boiling Liquid Expanding Vapor Explosion (BLEVE)**. The behavior of nitrous oxide liquid upon instantaneously relieving the pressure in a storage vessel with a burst diaphragm was observed and visually recorded through a window in the test vessel in a series of tests in a remote open-air test area, in an attempt to distinguish whether homogeneous nucleation of bubbles (the defining characteristic of a BLEVE) occurred at a specific test temperature between 250.9 and 271.5 K (−8.1 and +29.1 °F) [313, 314]. The question was also whether a physical explosion BLEVE can heat up the N_2O vapor sufficiently to initiate a chemical explosion. High-speed piezoelectric pressure transducers at the inside of the exhaust duct, above the burst disc, recorded a secondary pressure pulse that was believed to result from a rapid phase transition of the liquid nitrous oxide, releasing large quantities of N_2O vapor in a very short time interval. Close-up videos of the window showed that in all tests, nitrous oxide “ice” crystals were formed in the test vessel. Based upon the review of free-field high-speed pressure data, a BLEVE with the formation of a shock wave occurred when liquid nitrous oxide temperatures were 275 or 269.3 K (29 or 25 °F). A BLEVE was not evidenced when the liquid nitrous oxide temperatures were colder, at 256.2 K (+1.5 °F) and 250.9 K (−8.1 °F). The strength of the shock wave decreased as the liquid nitrous oxide temperature decreased. Even without a shock wave that may indicate a BLEVE event, a large volume of rapidly expanding gas was generated for all tests at all liquid nitrous oxide temperatures, between 250.9 and 271.5 K (−8.1 and +29.1 °F). The rapid phase change from liquid to vapor within 400 ms might have occurred via homogeneous bubble nucleation (characterizing a true BLEVE) or, alternatively, via heterogeneous nucleation promoted by nitrous oxide crystals. None of the rapid releases resulted in a chemical explosion.

9.3.3 Accident History of Nitrous Oxide

9.3.3.1 Explosion Accidents with Nitrous Oxide

A tank truck being loaded with subcooled liquid N_2O (relatively low pressure) exploded in Eindhoven, The Netherlands, on July 2, 2001. An accident investigation concluded that a not properly precooled centrifugal pump was running hot and started decomposition of the nitrous oxide vapor [315, 316]. Another theory believed that following the depletion of the liquid from the storage tank, the pump ran dry and overheated, thus igniting the vapor in the lines. The flame apparently flashed back into the tank, resulting in the rupture of the vessel. Gaseous nitrous oxide at >5.7 bar and in the presence of an ignition source can start a runaway reaction. Flashback into the tank car caused the tank to rupture. The remains of the accident are shown in Figures 45 and 46.

Figure 45: Post-accident scene of N_2O tank car explosion at Eindhoven, The Netherlands. (From [315].)

Early speculation about possible causes of the accident at Scaled Composites in California on July 26, 2007 suggested that the oxidizer tank of the propulsion system under development for Virgin Galactic's SpaceShipTwo suborbital rocket was the origin of the nitrous oxide explosion that killed three employees. The explosion occurred at the Rocky propulsion test site, which Scaled Composites rented from the Mojave Air and Space Port. One of the accident reports described the sequence of events as follows: "The workers had transferred the nitrous oxide from the [mobile conditioning system] into the propulsion equipment apparatus tank mounted on the test stand. The catastrophic explosion occurred about 3 s after the [cold nitrous oxide] flow began."

Information on nitrous oxide explosions during production and storage is not always very well documented. There is a report of an explosion of a gas bottle being filled

Figure 46: Remnants of N_2O tank car after tank car explosion at Eindhoven, The Netherlands. (From [315].)

with nitrous oxide gas in Berlin dating back to the year 1900 [317]. The gas bottle, presumably empty, heated up and exploded, which, in all likelihood, was caused by the presence of easily oxidizing organic contaminant compounds in it, but certainly not by N_2O decomposition.

A very detailed study sponsored by USAF in 1974 [202] made reference to “at least one instance of an unexpected and violent decomposition reaction” without revealing possibly classified details, but the incident(s) exposed the need for additional information defining the conditions under which N_2O can be decomposed and prompted an investigation into its safety and handling characteristics.

At about 1645 hours on Friday, July 6, 1973, a heated, pressurized tank of gaseous nitrous oxide exploded and burned on the B-8 test stand at Pratt & Whitney Aircraft at West Palm Beach, FL, where preparations were underway for testing an N_2O -CO laser combustor. Although there were no personal injuries, significant property damage occurred. A detailed description of the damage and test history was published [318]. The report contains numerous pictures of the damage, but unfortunately the pictures in the copy that could be downloaded from the internet were faded and could not be reproduced here. The pressure vessel holding the N_2O gas was made of 304 stainless steel, had walls that were 38 mm (1.5 in.) thick, and had four access openings. Both the supply line to the top and the run line from the bottom were connected to pressure relief valves set to open at 9.48 MPa gauge (1375 psig). The tank was reported to have been hydrostatically tested to its working pressure (12.4 MPa gauge at 294 K = 1800 psig at 70 °F) before the test. The tank and all components had been cleaned to

LOX standards. Four gas samples of N_2O from the run tank had been taken prior to the explosion, and the results of these analyses produced no evidence of decomposition while the gas was heated to 478 K (400 °F). Prior tests had used N_2O at 378 K (220 °F) and pressures up to 10.3 MPa gauge (1500 psig) without any undue events. The target conditions for this planned test were 478 K (400 °F) and 8.96 MPa gauge (1300 psig). In an effort to equilibrate temperatures in the run line prior to test, hot gas from the tank was admitted to a non-pressurized segment of the line. Approximately 5 s after the remotely operated valve signal light indicated an open position, system failure occurred. The 74-mm (3-in.) line at the top of the tank and both 3.1 mm (1/8 in.) threaded fittings holding pressure and temperature probes failed, resulting in large holes in the tank wall. Some damage occurred in the 51 mm (2 in.) run line: the Teflon seat of the valve disintegrated, and the stainless screen filter exhibited a few localized areas of ignition. The ball-bearing assembly of the flow meter was rendered inoperable due to complete burnout or disintegration of the bearing cage. The tank yielded about 5% in circumference, and the calculated pressure to achieve this yield was 41.4 MPa (6000 psig). It was postulated that opening a remotely operated valve allowed hot N_2O to suddenly pressurize the hot (413 K = 315 °F) ambient pressure nitrogen gas trapped in the run line between the valve and the laser reactor. Raising the pressure of this nitrogen isentropically to the tank pressure of 8.96 MPa gauge (1300 psig) would increase its temperature to 1366 K (2000 °F), well above the N_2O ignition temperature. The ignited N_2O could then burn back through the run line to the main tank and ignite the bulk of the mixture. There is another report of an explosion at a Puritan Bennett's (a medical gas supplier) manufacturing plant in Richmond, CA, in 1981 [319].

An explosion of a nitrous oxide trailer truck at an Airgas facility at Pensacola, Cantonment, Florida on August 8, 2016 resulted in one fatality and severe damage to the facility. It was determined that the explosion occurred due to overheating of the nitrous oxide pump during loading of the truck [305]. The feed to the Airgas nitrous oxide process was a by-product gas from a chemical manufacturing facility adjacent to the Airgas facility. This feed gas contained primarily nitrous oxide, nitrogen, oxygen, and carbon dioxide. At the time of the incident, Air Liquide owned and operated all five nitrous oxide manufacturing facilities in the United States and Canada. The Chemical Safety Board identified six previous major explosion incidents in the nitrous oxide industry that occurred before the explosion at Cantonment. Since 1973, the nitrous oxide industry has averaged one major explosion about every 7 years. These incidents killed 6 workers and injured 21 other people. Since 2001 these explosions have occurred more frequently, with an average of one explosion every 4 years during this timeframe.

9.3.3.2 Poisoning and Suffocation Accidents with Nitrous Oxide

The following information is lifted and quoted from CGA Fact Sheet and may require additional editing [320]. We quote verbatim:

Nitrous oxide fact sheet

What is nitrous oxide?

Nitrous oxide (N_2O) is a clear, colorless, oxidizing liquefied gas with a slightly sweet odor. The product is stable at room temperature. While classified by the US Department of Transportation (DOT) as a non-flammable gas, nitrous oxide will support combustion and can detonate at temperatures in excess of 650 °C (1202 °F). Contact your supplier to obtain a nitrous oxide Safety Data Sheet (SDS) for information on the safe handling and security of this product.

What are the principal applications of nitrous oxide?

Nitrous oxide finds beneficial use in a number of legitimate applications such as:

- Medical/dental anesthesia and analgesia
- Food processing propellant
- Semiconductor manufacturing
- Analytical chemistry
- Chemical manufacturing
- Auto racing engine injection

Nitrous oxide is blended with oxygen when used in anesthesia applications. Pure nitrous oxide will cause asphyxiation, resulting ultimately in respiratory arrest. Nitrous oxide in auto racing applications is denatured to deter inhalation. Nitrous oxide, used in food propellant applications, is typically supplied to commercial packagers of pressurized food dispensing containers.

Effects of nitrous oxide on the human body

Nitrous oxide's painkilling and numbing qualities begin to take effect when the gas is inhaled at concentrations of 10 percent. At increasingly higher concentrations, a sense of well-being, or "high," is experienced. A person experiencing a nitrous oxide high could:

- Have slurred speech
- Have difficulty in maintaining his or her balance or walking
- Be slow to respond to questions
- Be immune to any stimulus such as pain, loud noises, and speech
- Lapse into unconsciousness

Nitrous oxide that is inhaled accidentally over a long period of time at places of employment can lead to a vitamin B_{12} deficiency. When the level of vitamin B_{12} in the body is reduced, the red blood cell count is lowered, anemia results, and nerves degenerate. A vitamin B_{12} deficiency causes a person to have painful sensations in the arms or legs, have an unsteady walk or gait, become unbalanced and tend to fall over, feel or appear to be irritable, or even suffer intellectual deterioration.

What Are the Dangers?

Nitrous Oxide readily displaces air, causing asphyxiation. A person who is rendered unconscious by nitrous oxide is likely to stop breathing within a few seconds as a result of a depressed central nervous system, brain, brain stem, and spinal cord. Depression is caused by a combination of the effects of nitrous oxide and the lowered oxygen content that occurs as pure nitrous oxide displaces oxygen from the lungs with each succeeding inhalation of the gas; i.e., the person is asphyxiated.

Tragedy can occur very quickly. Long-term exposure (several minutes) is not necessary before death occurs. Sudden, prolonged exposure to high levels of nitrous oxide, or a series of inhala-

tions (without breathing clean air between inhalations) can result in death. The length of this action can be measured in seconds. Since the narcotic effect of nitrous oxide is very brief (several seconds) abusers tend to follow this repetitive action pattern.

If a person remains conscious and stops breathing the nitrous oxide, recovery (full consciousness and alertness) can occur within minutes. A person who loses consciousness, however, and continues to inhale a pure gas is most likely to die. Death usually occurs when abusers, in their attempt to achieve a higher state of euphoria, breathe pure nitrous oxide in a confined space, such as in a small room, inside an automobile or other vehicle cab, or by placing their head inside a plastic bag.

If death does not occur, the person who suffers from these symptoms may recover from all of them. The debilitating process is reversible, although some persons have experienced permanent loss of balance.

Abuse of nitrous oxide as an inhalant is on the rise, as is evidenced by the increased media attention to the subject. Its abuse has grown significantly at concert venues and on college campuses. Dealers will typically fill balloons with nitrous oxide and sell them. Police and other enforcement officials have found empty and/or discarded cylinders at the end of concerts. In some cases, dealers have removed required labels that identify cylinder contents and that provide information about safe use.

While most of the publicity regarding nitrous oxide abuse focuses on its occurrence at concerts, nitrous oxide abuse for recreational purposes is equally prevalent among individuals and small groups in settings far removed from the concert hall.

Theft of cylinders has made nitrous oxide available to people who are seeking the euphoric qualities of the gas, but who are unaware of the hazards of abusing nitrous oxide. People typically steal the cylinders from distributors or legitimate users or falsely represent themselves as legitimate users.

Guidelines to prevent nitrous oxide theft

CGA recommends the following guidelines for nitrous oxide sales and security. These guidelines are intended to help implement principles of product stewardship and to identify sufficiently responsible control measures that will minimize the theft of nitrous oxide and deter its abuse. These guidelines are established for the following groups:

PRODUCERS

Producers are anyone who produces nitrous oxide and then purifies, compresses, and liquefies this product for storage, shipment, and sale to a second party.

It is recommended that producers:

Establish a written sales policy that identifies legitimate applications for nitrous oxide, that may include but is not limited to medical, industrial, and food-based uses;

Restrict sale of nitrous oxide to those who can substantiate the legitimate use of nitrous oxide, as enumerated above;

Establish a written policy that clearly defines conditions for cash sales of nitrous oxide (e.g., all cash sales must be accompanied by a driver's license and a certified document that identifies the company or medical practice that will use the product);

Provide customers with a current SDS and any additional instructions for proper use and safe handling practices;

Provide this nitrous oxide fact sheet to customers;

Alert employees and customers to the dangers of nitrous oxide abuse.

Non-Bulk producers should keep an inventory of both full and empty cylinders and investigate any discrepancies.

Bulk producers (having large non-portable storage containers) should have a policy to investigate any tampering or vandalism of their bulk storage container.

COMMERCIAL CARRIERS

Commercial carriers are anyone who transports for hire nitrous oxide by road, rail, sea, or air.

It is recommended that commercial carriers:

Take appropriate steps to prevent the theft of nitrous oxide cylinders, both full and empty, since empty cylinders may contain residual product.

Keep cylinders in a secure area when on company premises.

Do not leave a delivery vehicle unattended without limiting access to nitrous oxide cylinders.

Keep an inventory of both full and empty cylinders and investigate any discrepancies.

Report any thefts promptly to the police and the shipper.

Alert employees to the dangers of nitrous oxide abuse and train them on the special security measures they should take to prevent its theft.

CONTAINER FILLERS OR DISTRIBUTORS

Container fillers and distributors are anyone who transfers nitrous oxide from a bulk vessel to cylinders, and anyone who sells nitrous oxide to medical, industrial, food, and other legitimate users.

It is recommended that container fillers or distributors:

Establish a written sales policy that identifies legitimate applications for nitrous oxide, that may include but is not limited to medical, industrial and food-based uses;

Restrict sale of nitrous oxide to those who can substantiate the legitimate use of nitrous oxide, as enumerated above;

Establish a written policy that clearly defines conditions for cash sales of nitrous oxide (e.g., all cash sales must be accompanied by a driver's license and a certified document that identifies the company or medical practice that will use the product);

Sell denatured (e.g., rendered unfit for human consumption) nitrous oxide for enhancing performance of internal combustion engines, so as to deter abuse;

Screen existing nitrous oxide accounts to assure that all are legitimate users of nitrous oxide;

Provide customers with a current SDS and any additional instructions for proper use and safe handling practices;

Provide this nitrous oxide fact sheet to customers;

Take the following steps to prevent the theft of nitrous oxide cylinders, both full and empty, since empty cylinders may also contain residual product:

Keep cylinders in a secure area when on company premises;

Do not leave a delivery vehicle unattended without limiting access to nitrous oxide cylinders;

Keep an inventory of both full and empty cylinders and investigate any discrepancies;

Report any thefts promptly to the police and the supplier;

Alert employees and customers to the dangers of nitrous oxide abuse and train them on the special security measures they should take to prevent its theft.

LEGITIMATE USERS

Legitimate users are anyone who can substantiate a medical, industrial, food, or other legitimate use for nitrous oxide.

It is recommended that legitimate users:

Minimize theft and indiscriminate use of nitrous oxide by storing containers and utilization equipment in a secured area subject to removal by authorized personnel only;

Keep an inventory of bulk product and or containers (both full and empty) and investigate any discrepancies;

Report any thefts promptly to the police and the shipper;

Use denatured (e.g., rendered unfit for human consumption) nitrous oxide, if required, for enhancing performance of internal combustion engines, so as to deter abuse;

Alert employees to the dangers of nitrous oxide abuse and train them on the special security measures they should take to prevent its theft;

Provide employees with a current SDS and any additional instructions for proper use and safe handling practices.

Contact your supplier to obtain a nitrous oxide Safety Data Sheet (SDS) for information on the safe handling and security of this product.”

10 Handling of Nitrous Oxide

10.1 Disposal of Nitrous Oxide

Disposal methods for nitrous oxide depend on the concentration of N_2O and diluents present. We need to differentiate between disposal of process streams that contain $>90\%$ N_2O or disposal of combustion products or exhaled air in operating rooms that may contain only less than 1% N_2O .

10.1.1 Abatement and Destruction of Nitrous Oxide in Stack Gases

Nitrous oxide in combustion products and stack gases from industrial power plants is a contaminant that is more difficult to remove than NO_x . Nitrous oxide is a greenhouse gas that contributes to global warming. For this reason, methods are sought to remove N_2O from stack gases along with the more reactive $\text{NO}/\text{NO}_2/\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ gases. Prior to the concern about greenhouse gases, a substantial effort was implemented to remove NO_x from stack gases, sometimes using ammonia, cyanuric acid, or urea as reductants in a so-called *selective non-catalytic reduction* process. While this process achieved the initial objective of NO_x reduction, it at the same time created a new problem by increasing the N_2O emissions. Thus, additional technology was sought to remove N_2O from stack gases. Undiluted nitrous oxide that is no longer needed or has become contaminated should not simply be vented to the atmosphere where it would aggravate the problem with global warming due to greenhouse gases. The gas can be fed to a flare torch and burned with natural gas or propane (and releasing CO_2 , which is not as bad as N_2O). Reburning with hydrogen, carbon monoxide, methane, or ethylene in a jet-stirred reactor has been studied as a means of N_2O destruction in stack gases [321].

Instead of consuming a valuable fuel like methane in the removal of nitrous oxide, it would be less energy intensive to pass the stack gases over a catalyst that decomposes the nitrous oxide into harmless nitrogen and oxygen. It turns out that catalysts

developed for industrial N_2O removal may also be useful as catalysts for rocket engines using N_2O as a monopropellant and vice versa.

Instead of simply thermally preheating the gases that have to be purified of N_2O one can pass them through an arc discharge. The presence of catalysts in this plasma-catalytic N_2O removal process greatly accelerated the rates of N_2O destruction [322]. A rotating arc discharge, combined with a catalytic bed, has been tested for nitrous oxide removal in oxygen-containing stack gases. It has been found that under conditions of a rotating arc, nitrous oxide in mixtures with oxygen or air not only decomposed to oxygen and nitrogen but was also oxidized to nitric oxide. The overall conversion of nitrous oxide, as well as the degree of N_2O oxidation to NO , were studied as a function of its initial concentration, flow rate, and discharge power. The overall N_2O conversion and degree of oxidation to NO decreased with increasing flow rate and initial N_2O concentration and increased with increasing discharge power. The degree of N_2O oxidation to NO varied within 20–37%. The overall conversion and degree of N_2O oxidation increased when granular dielectric materials (TiO_2 , SiO_2 , $\gamma\text{-Al}_2\text{O}_3$) were introduced into the reaction zone. The energy efficiency and the overall conversion of N_2O were still further increased due to catalytic effects of a number of metal oxides (CuO , NiO , MnO_2 , Fe_2O_3 , Co_3O_4 , ZrO_2) deposited on $\alpha\text{-Al}_2\text{O}_3$. The activity of the oxide catalysts decreased in the order: $\text{CuO} > \text{Fe}_2\text{O}_3 > \text{NiO} > \text{MnO}_2 > \text{Co}_3\text{O}_4 > \text{ZrO}_2$. It has been suggested that the combined plasma-catalytic processing may be an efficient way to reduce N_2O emissions.

The thermal (non-catalytic) decomposition of N_2O was studied in order to establish an industrial process for N_2O abatement in an adipic acid production plant. N_2O from an adipic acid plant was decomposed in a plug-flow reactor under atmospheric pressure at temperatures of less than 1500 K [323]. For a model simulating the conversion of N_2O and NO , it was assumed that the reaction was carried out in an adiabatic reactor incorporating a completely uniform mixing system. The results of the simulation indicated that N_2O at concentrations between 30 and 50 vol-% is spontaneously decomposed into N_2 , O_2 , and NO at a reaction temperature between 1273 and 1473 K by using its own heat of reaction.

10.1.2 Removal of Nitrous Oxide in the Air in Operating Rooms

The gas administered to patients for anesthesia may contain up to 70 vol.-% N_2O with the rest being oxygen. A majority (70%) of patients achieved ideal sedation with between 30 and 40% N_2O . The exhaled air from patients may contain up to 50 vol.-% N_2O . Because nitrous oxide is minimally metabolized in humans (with a rate of 0.004%), it retains its potency when exhaled into the room by the patient and can pose an intoxicating hazard to the attending clinic staff if the room is poorly ventilated. If the exhaled air diffuses into the ambient air in the operating room, and the room is not properly ventilated, N_2O concentrations can build up to a level where they begin to affect medical personnel attending to the patient. Methods have been sought to remove N_2O from the air in operating rooms [324, 325].

10.1.3 Disposal of High Concentrations of Nitrous Oxide

If liquid nitrous oxide intended to be used in a flight application in the Airborne Laser Laboratory is no longer needed, it has to be dumped overboard because the aircraft cannot land safely with the extra propellant mass on board, and a contingency plan for in-flight dumping of N_2O has to be developed. The problem is that the liquid may freeze as soon as it expands and clog the discharge orifices. The sudden accidental freezing of liquid N_2O during rapid discharge from an airborne tank would prevent the aircraft from dumping the unwanted propellant in order to reduce its touchdown mass. The freezing of flowing N_2O has been studied in several oxidizer dump tests [91, 92]. Analysis of the liquid dumping showed that solidification of the liquid N_2O might occur if the pressure in the line falls below 87 kPa (12.7 psia). Flow experiments were run with the liquid N_2O dumping into a large vacuum chamber that simulated the high-altitude environment during flight. In seven tests, 6–12 kg (12–24 lb_m) liquid N_2O were expelled either under its own vapor pressure or with helium pressurant 8.27 MPa (1200 psia) in the ullage space above the liquid. The flow rates were 1.45 to 3.6 kg/s (3.2 to 8 lb_m/s). The piping configuration used in the tests was identical to that of the airborne system. The tests showed that the pressure at the dump line exit remained above 87 kPa (12.7 psia) for all conditions tested; therefore, no solidification occurred in the lines. The N_2O transformed to snow after it exited from the dump line and entered the vacuum chamber.

11 Other Uses of Nitrous Oxide

Most books with the title “Nitrous Oxide” deal only with the medical use of nitrous oxide as an analgesic and anesthetic agent [326, 327]. The main uses for nitrous oxide are in medicine as an analgesic and anesthetic agent and in food chemistry as a pressurant and foaming agent for whipped cream in spray cans. It is preferred over other pressurants for food application because it is bacteriostatic (stops bacteria from growing) and leaves no taste or odor in the whipped cream. Nitrous oxide was used as a refrigerant in the past, but that use has been discontinued. Although it has a relatively high ozone depletion potential, it is still better than some of the halocarbons it was intended to replace for low-temperature refrigeration. ASHRAE, in a recent version of Standard 34.1 designates it as R744a or R744A. An extremely pure grade of nitrous oxide is used for etching semiconductors.

Nitrous oxide injection is used in “souped up” racing cars for increased performance [328]. Nitrous oxide for racing car use is denatured with an odorant to discourage inhalation. There are images on the internet of racing cars bursting in flames after being “souped up” by nitrous oxide injection.

Noble Gas Fluorides

Until half a century ago, generations and generations of chemists were taught that gases in IUPAC Group 18 of the periodic table of elements will not enter into **any** chemical reactions. They were a class by themselves, they did not want to mingle with common elements, and therefore they were called “noble” gases. This changed in the 1960s, when in short succession fluorides, oxyfluorides, hydroxides, and oxides of xenon and krypton were synthesized, and those events opened new vistas on the nature of the chemical bond. Chapters in many chemistry textbooks had to be rewritten after this discovery. The section at hand contains only a short summary of literature references reflecting the excitement that prevailed among fluorine chemists in the 1960s when the first noble gas fluorides were discovered. Many more publications have appeared in the interim, but listing them all would fill an entire book by itself.

To date, noble gas compounds have been mostly a chemical curiosity and have not found industrial applications (except some noble-gas/fluorine mixtures in lasers). Most of the noble gas compounds are solids that cannot be used in liquid rocket engines. Although xenon is now used as a working fluid in electric rockets, the limited supply of the heavier noble gases will prevent the use of these compounds as chemical rocket propellants. We list them here only in the hope that one of these days the fluorides and oxides of the lighter noble gases, such as argon, neon, or even helium (!!), will be synthesized and tested as rocket propellants (as unlikely that seems to be possible at this time). Noble gas fluorides are listed here only because the study of noble gas fluorides has provided a better understanding of the chemical bond in all covalent fluorides, and that knowledge benefits the synthesis of other fluorides, which may be suitable as rocket propellants.

Along with noble gas fluorides, noble gas oxides and oxyfluorides have been synthesized. Noble gas oxyfluorides, ternary noble gas/oxygen/fluorine compounds, will be discussed in a separate, subsequent chapter of this book. If they could be made cheaply, they should also be evaluated as rocket propellants.

There are many summary publications on the chemistry of noble gas fluorides, and only a few are given here [1–7]. In addition to binary noble gas fluorides, there are also ternary noble gas compounds containing both oxygen and fluorine.

A historical (not up-to-date) summary of observed properties of some noble gas fluorides is given in Table 1.

1 Preparation of Noble Gas Fluorides

A substantial amount of high-energy activation is required to get noble gases to react with elemental fluorine. Methods used are high pressure combined with high temperature, glow discharge, UV photolysis, and laser irradiation.

Table 1: Historical summary of first properties of noble gas fluorides reported in the literature.

Compound name	Chemical formula	Properties	References
Krypton difluoride	KrF ₂	So far only seen spectroscopically, short-lived	[8]
Krypton tetrafluoride	KrF ₄	Colorless, clear crystals, vapor pressure somewhat higher than that of XeF ₄ , thermally less stable than XeF ₄ , sublimates at 233 to 243 K (–40 to –30 °C) in vacuum	[9, 10]
Xenon difluoride	XeF ₂	Colorless, clear crystals, heat of sublimation 51.5 ± 0.8 kJ/mol (12.3 ± 0.2 kcal/mol)	[11–16]
Xenon tetrafluoride	XeF ₄	Colorless, clear crystals, can be sublimed undecomposed in vacuum. Melting point above 373 K (100 °C), heat of sublimation 64.0 kJ/mol (15.3 ± 0.2 kcal/mol), Molar heat capacity $C_p = 188$ J mol ^{–1} °C ^{–1} (45 cal mol ^{–1} °C ^{–1}), Entropy $S_{298} = 360$ J mol ^{–1} °C ^{–1} (85.9 cal mol ^{–1} °C ^{–1})	[17–20]
Xenon oxyfluoride	XeOF ₂	Colorless crystals	[9]
Xenon hexafluoride	XeF ₆	Colorless crystals, melting point 319 K (46 °C), vapor pressure at 273 K = 0 °C: 1 kPa = 7.5 mm Hg, at 298 K = 25 °C: 4 kPa = 30 mm Hg, turns yellow at temperatures above 315 K = 42 °C in all physical states; Other sources gave the melting point as 322.63 ± 0.10 K, and the enthalpy of fusion as 5743 J/mol.	[21, 22]
Radon fluorides		Not yet identified for sure	

This table has not been updated and is included here only as part of a historical account of noble gas fluorides.

The photolysis by laser radiation (488 nm) of Kr, Xe, O₂, and UF₅ dissolved in liquid fluorine resulted in the formation of KrF₂, XeF₂, O₄F₂ or O₂F₂, and UF₆, respectively [23]. No reaction product was observed as the result of laser photolysis of liquid fluorine saturated with Ar, N₂, IF₅, RuF₅, or OsF₆.

1.1 Preparation of Xenon Fluorides

It appears that the walls of Monel pressure vessels in which the high-pressure synthesis of xenon fluorides is carried out have a distinct catalytic effect on the reaction [24]. The formation of xenon fluorides is not a homogeneous gas-phase reaction. The reactions are heterogeneous and occur for the most part on the fluorinated walls of the Monel reaction vessels. CoF₃ or NiF₂ also exhibited catalytic activity in fluorine-xenon reactions. See also [25–29].

1.2 Preparation of Krypton Fluorides

Krypton fluorides can be prepared using methods similar to those used for xenon fluorides [30, 31].

2 Physical Properties of Noble Gas Fluorides

The physical properties and molecular structures of noble gas fluorides have often been derived from optical or X-ray diffraction (XRD) measurements [32–41].

2.1 Thermodynamic Properties of Noble Gas Fluorides

Although noble gas fluorides are not likely to be used as rocket propellants, their thermodynamic properties have been summarized here just in case someone wants to run theoretical rocket performance calculations. Knowledge of thermodynamic properties also will help to predict the thermal stability of these compounds under different temperature and pressure conditions and will help optimize the conditions for the formation of these compounds during their synthesis from the elements [42, 43].

The standard entropy of formation of solid XeF_4 at 298 K was found to be $-407.95 \pm 0.17 \text{ J K}^{-1} \text{ mol}^{-1}$, and the standard Gibbs energy of formation at 298 K was $-145.48 \pm 0.88 \text{ kJ/mol}$ [44]. The corresponding quantities for gaseous XeF_4 at 298 K were $-250.97 \pm 0.40 \text{ J K}^{-1} \text{ mol}^{-1}$ and $-131.36 \pm 0.91 \text{ kJ/mol}$. The standard enthalpies of formation of the solid and of gaseous xenon tetrafluoride at 0 K were $-266.29 \pm 0.88 \text{ kJ/mol}$ and $-201.39 \pm 0.90 \text{ kJ/mol}$, respectively. The equilibrium constant for the formation of gaseous XeF_4 from the elements at various temperatures was tabulated and compared with experimental measurements.

The melting point of XeF_6 is $322.63 \pm 0.10 \text{ K}$, and the enthalpy of fusion is 5743 J/mol . The vapor pressure of the liquid between 323 and 350 K can be calculated by

$$\log P = -6170.88/T - 23.67815 \log T + 80.77778$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin. The high entropy of vaporization ($136.9 \text{ J K}^{-1} \cdot \text{mol}^{-1}$) at the boiling point (348.72 K) and the high and rapidly rising heat capacity of the liquid suggest that the liquid is associated [45]. Thermodynamic functions of the condensed phases were tabulated at various temperatures. At 298 K the values of C_p° , S° , $H^\circ - H0^\circ$, and $(G^\circ - H0^\circ)/T$ for solid XeF_6 were $171.59 \text{ J K}^{-1} \text{ mol}^{-1}$, $210.38 \text{ J K}^{-1} \text{ mol}^{-1}$, 30999 J/mol , and $-106.41 \text{ J K}^{-1} \text{ mol}^{-1}$, respectively. At 355 K the standard entropy S° was $255.5 \text{ J K}^{-1} \text{ mol}^{-1}$ for liquid XeF_6 and $402.6 \text{ J K}^{-1} \text{ mol}^{-1}$ for the gas.

2.2 Chemical Properties of Noble Gas Fluorides

2.2.1 Complex Salts with Noble Gas Fluorides

Reactions of xenon hexafluoride with tin(IV) fluoride [46], germanium tetrafluoride or silicon tetrafluoride, [47] and arsenic pentafluoride or phosphorus pentafluoride [48] result in the formation of complex salts of the XeF_5^+ cation.

The IR and Raman spectra of solid $\text{XeF}_5^+\text{BF}_4^-$ and $\text{XeF}_5^+\text{AsF}_6^-$ and their Raman and ^{19}F NMR spectra in HF solution were recorded [49]. The observed spectra were consistent with a square-pyramidal XeF_5^+ cation of symmetry C_{4v} .

Xenon tetrafluoride forms stable 1:1 adducts with $(\text{CH}_3)_4\text{NF}$, CsF, RbF, KF, and NaF [50]. These adducts are salts containing a planar pentagonal pentafluoroxenate(IV) XeF_5^- anion, as shown by XRD crystal structure determinations and IR, Raman, and NMR spectra.

Noble gas fluorine oxidizers of neon, krypton, argon, and xenon have been synthesized and characterized, and KrF^+ and XeF^+ cations have been made with neutral organic bases. Even Kr-N and Kr-O bonded molecules were synthesized and characterized and the hypervalent compound XeF_5^- was made [51–53]. See also [54].

3 Ternary Fluorides

By way of definition, we call binary fluorides those that contain only one type of atom that is different from fluorine. Examples are ClF_3 and NF_3 . We call ternary fluorides those compounds that contain two different atoms other than fluorine. Examples are XeOF_4 and XeO_2F_4 .

4 Noble Gas Oxyfluorides

Along with noble gas fluorides, the discovery of noble gas oxides and noble gas oxyfluorides has opened a new chapter of fluorine chemistry. Both are theoretically energetic rocket propellant oxidizers, but they are not practical because they are available only in limited quantities. It would be desirable to make similar compounds with argon, but that has not yet been accomplished.

4.1.1 Preparation of Noble Gas Oxyfluorides

Xenon oxide tetrafluoride, also known as xenon fluoride oxide, XeOF_4 , CAS RN [13774-85-1], can be prepared by partial hydrolysis of XeF_6 using either dynamic or static methods. In the static methods XeF_6 is reacted with either H_2O or SiO_2 . These reactions, particularly on a larger scale, are very hazardous and, unless great care is exercised, can result in violent explosions due to the localized accumulation of highly

explosive XeO_3 . This hazard of the static methods can be diminished somewhat by the dynamic method of bleeding air saturated with water vapor into a circulating loop filled with XeF_6 vapor and monitoring the XeF_6 consumption by IR. The reaction of NaNO_3 with a slight excess of XeF_6 provides a convenient, one-step synthesis of XeOF_4 according to [55]

Alkali metal nitrates and NO_2 are useful reagents for the stepwise replacement of two fluorine atoms by one oxygen atom in xenon fluorides or oxyfluorides. Thus, the reaction of an excess of XeF_6 with CsNO_3 yields XeOF_4 , FNO_2 , and CsXeF_7 . The reaction of XeF_6 with CsNO_3 in excess gave CsXeOF_5 and FNO_2 , and after longer reaction times some CsXeO_2F is also formed. The reaction of CsNO_3 with an excess of XeOF_4 produced mostly FNO_2 and XeO_2F_2 but also CsF and CsXeOF_5 as byproducts [56, 57].

4.1.2 Physical Properties of Noble Gas Oxyfluorides

Xenon dioxide tetrafluoride, XeO_2F_4 , CAS RN [15195-51-4], was made by the reaction

and identified by mass spectroscopy [58]. It is the most volatile of the known xenon compounds and may therefore possess the symmetrical, non-polar, D_{4h} symmetry. XeO_3F_2 , which originally was made by the reaction of XeF_6 with Na_4XeO_6 , can be made in much better yield by the reaction of XeF_6 with XeO_4 . It is destroyed by more than brief contact with XeF_6 , being converted to XeOF_4 .

The microwave spectrum of XeOF_4 has been measured in the 20–40 GHz range [59, 60]. Transitions were observed for five naturally occurring isotopes of xenon in the ^{16}O species and for two of these isotopes in an ^{18}O -enriched sample. The data support a C_{4v} symmetry for this molecule.

4.1.3 Chemical Properties of Noble Gas Oxyfluorides

Xenon oxide tetrafluoride is a clear, colorless liquid freezing at 224.9 K (-48.2°C) [61]. Its electrical conductivity at 297 K (24°C) is $1.03 \times 10^{-5} \text{ ohm}^{-1} \text{ cm}^{-1}$, and its dielectric constant is 24.8 at 297 K (24°C). It is miscible with anhydrous HF, but its conductivity is not enhanced in such a solution. The addition of CsF or RbF to XeOF_4 increased its conductivity markedly. Xenon oxide tetrafluoride formed a series of addition compounds with the heavier alkali fluorides. The following complexes have been isolated: $\text{CsF} \cdot \text{XeOF}_4$, $3\text{RbF} \cdot 2\text{XeOF}_4$, and $3\text{KF} \cdot \text{XeOF}_4$. Xenon oxide tetrafluoride reacted with SbF_6 to form a complex of composition $\text{XeOF}_4 \cdot 2\text{SbF}_6$. A reaction also occurred with AsF_5 at 195 K (-78°C), but the complex was unstable at room temperature.

Oxygen

Introduction

Among the oxygen-containing oxidizers we count molecular dioxygen, O_2 , ozone O_3 (“trioxygen”), and also hydrogen peroxide, $H-O-O-H$, a compound that contains an oxygen-oxygen peroxide link. Of course, many other oxidizers contain oxygen but it is bound in some form or another to a non-oxygen central atom like nitrogen or chlorine. Beyond those oxygen compounds well known and thoroughly characterized, we need to look at other oxygen species that are either short-lived at room temperature or can be stabilized at low temperatures. Other poly-oxygen species are either purely speculative, exist only in the mind of some researchers or on paper and computer printouts, but nevertheless it would be tempting to evaluate them as rocket propellants. Some are predicted to exist only at very high pressures, pressures not typically encountered in a rocket engine. *Encyclopedia of Oxidizers*, chapter “Oxygen” and chapter “Ozone” discuss poly-oxygen species either in relation to dioxygen or to ozone.

1 Oxygen

Liquid oxygen, correctly named liquid dioxygen, CAS RN [7782-44-7], commonly abbreviated as LOX (from **L**iquid **O**Xygen), has been the most important rocket propellant oxidizer since the early days of rocketry. It has maintained this leading position for almost a century and in all probability will maintain this position in the future as well. The reason is the unlimited availability of oxygen, which is a constituent of atmospheric air on Earth. Atmospheric air on Earth contains 20.8 vol.-% oxygen, which can be readily separated from nitrogen and the other air constituents.

Oxygen is the most abundant element in the Universe after hydrogen and helium, and therefore it is expected to be present in the solid phase in giant gas planets and “icy” grain mantles of comets and interplanetary particles. Being able to find dioxygen (or oxygen in the form of water) on any extraterrestrial body that might be a destination for future space travel or even planetary colonization would be a great bonus to in-situ resource utilization (ISRU).

2 Production and Availability of Liquid Oxygen

Air separation and liquefaction technology is a mainstay of cryogenic engineering and does not have to be explained here in detail. Most air separation and liquefaction plants produce both liquid oxygen and liquid nitrogen and capture some argon and other noble gases as by-products. Other methods for preparation of oxygen are pressure-swing absorption (up to 90% O_2) and solid electrolyte oxygen separator

(SEOS) technology. An SEOS breadboard demonstration unit was capable of generating >99.9% oxygen at pressures up to 15.1 MPa (2200 psig) using electric power [1, 2]. The oxygen was stored in high pressure cylinders and analyzed per US MIL-PRF-27210. The SEOS method would be suitable for remote locations where cryogenic oxygen as breathing oxygen for military pilots is not available.

Logistics of liquid oxygen for rocket test and launch sites in remote areas require advance planning. Most of the medium-scale portable LOX production equipment is for breathing air for pilots in military airplanes based in remote airfields and not for rocket applications. There are pallet-mounted air separation and liquefaction plants that can be flown in by airplanes, assembled in a few hours, and can generate 360 kg LOX/h [3]. Other LOX generators can be mounted on a semitrailer for transportability [4]. Other generators that can be transported by road or rail have production capacities of 75 metric tons/day and take 5 h to come up to speed. Stationary installations can have capacities of up to 150 metric tons/day [5].

The Joule-Thomson coefficient determines how much a gas cools off or warms up as it expands through a restriction. For the Joule-Thomson effect to take place, the initial gas temperature must be below its inversion temperature. The inversion curve in a temperature-pressure diagram separates regions of positive and negative Joule-Thomson coefficients (Figure 1). The Joule-Thomson coefficient along this curve is

Figure 1: Joule-Thomson inversion curve for oxygen (reproduced and modified from [6])

zero. If the properties of various non-associated, non-polar gases are plotted in terms of their reduced pressure and reduced temperature (properties normalized by their critical point properties), they all share the same inversion curve [6]. There are two inversion temperatures for every pressure. The Joule-Thomson inversion point of oxygen is near 350 K at 58 MPa.

The basic oxygen liquefaction cycle is the Linde-Hampson cycle with variations and improved performance cycles. Alternative liquefaction cycles are the Claude and Collins cycles.

The ideal work required for liquefaction of oxygen beginning at 300 K and 101.3 kPa is 635.6 kJ/kg. The actual optimized theoretical energy requirement of a Linde-Hampson liquefaction cycle is 3804 kJ/kg. The energy consumption for production of one metric ton of LOX from air is approximately 920 kWh. Starting with pure oxygen gas instead of air will reduce the energy consumption to 173 kWh/Mg. Estimates dating back to 1973 for liquefaction work were 630 kWh_e/ton for liquid oxygen and 662 kWh_e/ton for liquid nitrogen, from a production facility that was about 25 and 29% Carnot efficient, respectively.

Liquid and gaseous oxygen is produced in an energy-intensive air separation process that also generates nitrogen. More than 65% of the cost of oxygen is attributable to energy costs [7]. Air separation plants can produce more than three times more nitrogen than oxygen, but present markets demand, at most, only 1.5 times more. Full utilization of liquid and gaseous nitrogen should be encouraged, so that the wasted separation energy is minimized. There are potential markets for nitrogen in production of ammonia for fertilizer.

The largest oxygen consumer (approx. 65% of total oxygen production as of 1979) is the steel industry [8]. If steel plants do not have their own liquid oxygen plant on site, they will often have the oxygen delivered by tank car in liquid form or by pipeline in gaseous form. Rocket technology, steel works and hospitals use a common liquid oxygen supply infrastructure.

The daily production of liquid oxygen in the world was estimated to be 70000 metric tons/day in the 1960s. The annual LOX consumption of the rocket industry peaked in 1966 at 600000 metric tons. This was the time when the F-1 engine and the SATURN-V stages underwent static testing. For a test duration of 150 s, a single F-1 engine would typically consume 500 metric tons of LOX (although some of this was due to evaporation losses during cooldown).

3 Physical Properties of Oxygen

Under normal conditions, oxygen (dioxygen, O₂, CAS RN [7782-44-7]) is a colorless and odorless gas that condenses at 90 K (−183 °C) to form a pale blue liquid. The faint blue tinge can also be observed in liquid air that has been sitting around for a while, allowing the lower boiling, more volatile nitrogen to evaporate first, leaving oxygen behind

and allowing some atmospheric oxygen to condense into the mixture. The molecular mass of dioxygen is 31.9988 g/mol (NIST Chem WebBook).

Physical properties of oxygen and other propellants can be calculated on-line with the reference fluid thermodynamic and transport properties (REFPROP) program developed by the National Institute of Standards and Technology (NIST) [9, 10].

In providing a summary of physical properties of oxygen in the following sections, no effort has been made to evaluate the reliability and accuracy of the data collected from various sources in the literature. The data are shown here in juxtaposition and where more than one source of data is available, the readers will have to decide for themselves which data set fits their application more closely. In many cases the physical properties data are shown in tabular and/or graphical format and, in addition, where possible expressed as polynomial functions of temperature and/or pressure that one can plug into a spreadsheet to generate a more detailed printout of physical properties in increments of one degree of temperature.

Additional data on the physical and thermodynamic properties data of oxygen in various physical states can be found in the references listed in Table 1 and several other tables further down in this chapter.

Table 1: Literature sources on the physical and thermodynamic properties of oxygen.

During the period 1998–1999, the Chemical Propulsion Information Agency (CPIA) released four versions of Cryogenics Information Retrieval System in CD form, including the National Bureau of Standards (NBS) Cryogenics Database, which had not been updated since the early 1980s and a wide range of other literature sources, eventually containing 133000 citations [25].

3.1 Freezing Point and Phase Transitions of Oxygen

3.1.1 Freezing Point of Liquid Oxygen

The parameters characterizing melting of oxygen at the triple point (anomalously low volume jump during melting, fusion entropy, and saturated vapor pressure) distinguish it (along with fluorine) from the simplest molecular systems. The assumption that the γ -O₂ chain structure is preserved in liquid oxygen in the form of a short-range order provides a satisfactory explanation for the observed anomalies. Freezing point data for liquid oxygen are summarized in Table 2.

Figure 2: Melting point of solid oxygen as a function of pressure (reproduced and modified from [34])

Solid oxygen will melt at much higher temperatures than 54 K if it becomes pressurized to very high pressures in the order of thousands of atmospheres, as illustrated in Figure 2, based on reference [34].

3.1.2 Phase Transitions of Solid Oxygen

At low temperature and pressures near one atmosphere, three phases of solid oxygen are observed, α , β , and γ . The high temperature γ -phase is stable from the melting point (~ 55 K) down to 43.8 K, where it transforms to the β -phase and is not observed in matrices due to its high vapor pressure. The rhombohedral β -phase converts to the α phase at 23.880 K. The α -phase is monoclinic and the transition from β to α is driven by strain, induced through magnetic interactions with only a small heat of transition. The existence of $\alpha\delta$ phase has been suspected. Considerable experimental effort has gone into the investigation of the solid phase transition temperatures of oxygen because the transitions might be useful as secondary fixed points in thermometry [35]. The triple point of oxygen is the primary fixed point of the International Temperature Scale of 1990 and $\beta \rightarrow \gamma$ and $\alpha \rightarrow \beta$ phase transitions were recommended as secondary fixed points.

Oxygen occurs in at least three, possibly four solid modifications. The structure of α -oxygen was determined by XRD to be monoclinic. The structure of β -oxygen determined from electron diffraction data is rhombohedral. The structure of γ -oxygen was determined by XRD to be cubic. The structure of the δ -solid, if it is verified, is not known [36].

A quasi-harmonic lattice dynamics method coupled with a pattern recognition optimization scheme was used to determine the minimum energy structures and magnetic orientations of solid oxygen [37]. It was shown that the magnetic interaction is responsible for the stability of α O₂ with respect to β -O₂ at zero temperature and pressure. The calculated α O₂ lattice parameters, magnetic orientations, and sublimation energy were in good agreement with experimental data.

Phase transitions in solid oxygen at pressures up to 13 GPa at 298 K were studied by XRD [38, 39] and Raman spectroscopy [40].

Two important factors determine the mechanism and temperature of the $\alpha \rightarrow \beta$ phase transition in solid oxygen: the magnetoelastic coupling, which increases the temperature of the transition and the anti-ferromagnetic order in the β -phase, which stabilizes this phase at low temperatures, thus lowering the transition point [41]. It has been shown that the competition between magnetic and elastic forces leads to an instability of the crystal and, consequently, to the phase transition. The $\alpha \rightarrow \beta$ transition is a first-order reaction.

Solid oxygen is a unique crystalline material combining properties of a simple molecular solid and of a magnet [42]. Unlike ordinary magnets, the exchange interaction in solid oxygen acts on a background of weak van der Waals forces, providing a significant part of the total lattice energy. The magnetic and lattice properties in solid oxygen are very closely related and result in a very complex phase diagram and in nu-

merous anomalies of thermal, magnetic, and optical properties. Diamond anvil cell studies have extended the phase diagram of solid oxygen to the pressure range over 200 GPa and temperatures over 1000 K, thereby revealing an astonishing variety of phases. Pressure-induced changes in crystalline structures are accompanied by modifications of the optical properties. From a light blue transparent crystal, oxygen turns orange and then red at approximately 10 GPa. Upon further compression, the crystal gets darker and becomes nearly opaque to visible light at around 40 GPa. This color change, which is an evident example of how compression can perturb the electronic states of a simple molecule, is a peculiarity of solid oxygen and does not occur in any other diatomic molecular solids. At 96 GPa solid oxygen transforms to a metal retaining the diatomic molecular structure. At low temperatures of 0.6 K and 96 GPa metallic oxygen becomes superconducting. The enthalpy change during the $\alpha \rightarrow \beta$ transition taking place at 23.8 K has been measured by dozens of investigators and varies widely from 73 to 103 J/mol. The structural rearrangement at the $\beta \rightarrow \gamma$ transition at 43.8 K is so essential that the latent heat of transition (742 J/mol) is even larger than the heat of fusion of oxygen. The exact temperature of this transition, 43.7964 ± 0.0002 K, has been defined as a secondary fixed point of the International Temperature Scale of 1990 (ITS 90).

The various phases of solid oxygen have been identified with Greek letters ranging all the way from α to ϕ and beyond, some of which are only encountered at very high pressures up to 20 GPa [43].

The phase transition into β -O₂ occurs at $T = 17.75 \pm 0.2$ K [44]. It is first order with a calculated volume change $\Delta V = 0.06 \pm 0.10$ cm³/mol and is accompanied by a magnetic transition into a highly dynamic quasihelical state with a correlation length $l_c = 8 \pm 1$ Å at 18 K, that decreases rapidly with increasing temperature. The results indicated that O₂ behaves as a two-dimensional magnetic system.

Crystal structures of solid oxygen will be discussed in section “Crystal Structure of Solid Oxygen” further down in this chapter. Solid oxygen can serve as a matrix and stabilizer for solid ozone [45].

In situ high pressure-high temperature Raman measurements and optical observations of solid and fluid oxygen up to 1250 K between 8 and 25 GPa revealed the existence of a new molecular phase η and strikingly unusual behavior of the melting curve [46]. Three triple points were also identified in the P - T domain of the new phase.

Based on Raman scattering and infrared absorption at low temperatures results, a revised phase diagram of thermodynamically stable oxygen has been proposed [47]. In the revised phase diagram, the α phase existed up to temperatures of the β phase and up to a pressure of about 6 GPa, where a clear first-order transition to the δ phase occurred.

Solid oxygen might be encountered in a rocket by accident if the oxygen supply line runs through the liquid hydrogen tank or the two lines run parallel and too close to each other. This would be a very undesirable situation. It is possible that frozen oxygen exists on other gas giant planets in orbit around some distant stars. It is also

possible that frozen oxygen in those planets exists under extremely high pressures. Frozen oxygen under extremely high pressures is unlikely to be encountered in any type of rocket operation, but it is interesting to briefly mention the unusual behavior of frozen oxygen at extremely high pressures. Speculation and a bit of imagination could lead to the suggestion that compressing oxygen could irreversibly lead to new forms of super-oxygen denser and more powerful, but thermally more stable than ozone that could be used as a high-energy, readily available rocket propellant oxidizer. Unusual arrangements of oxygen atoms and dioxygen molecules under high pressures can lead to molecular structures of dioxygen dimers (O₂)₂, trimers (O₂)₃, and molecular oxygen tetramers (O₂)₄, all candidate rocket propellants. Frozen oxygen would be the first choice of oxidizers for cryogenic solid propellants. An inverse hybrid rocket engine firing a mixture of frozen oxygen and gaseous hydrogen was tested at the United States Air Force Phillips Laboratory with promising results.

Slush oxygen, that is a mixture of solid and liquid oxygen, has been considered as an alternate to liquid oxygen in rocket propulsion primarily because the density increases in going from liquid to mixtures of liquid and solid. In 2015, Space-X began flying subcooled oxygen in its Falcon launch vehicles. The higher density of subcooled liquid oxygen allowed them to load more oxidizer in the same size tank.

3.2 Boiling Point of Liquid Oxygen

Boiling point data for liquid oxygen are summarized in Table 3. The boiling point of oxygen was a reference point on the International Practical Temperature Scale.

Table 3: Boiling point of liquid oxygen.

3.3 Density and Partial Molar Volumes of Liquid Oxygen

3.3.1 Density of Liquid Oxygen at Atmospheric Pressure

Density data for solid and liquid oxygen are listed in Table 4.

Table 4: Density of solid and liquid oxygen.

State	Temperature		Density	Authors	Year	References
	K	°C				
Liquid	85	−188	1.1671	Baly and Donnan	1902	[49]
Liquid	77.6	−195.5	1.2019 ± 0.0009	Jenkins and Dipaolo	1956	[50]
Liquid	77.5	−195.6	1.204 ± 0.004	Emelyanova, Strakhov, and Lebedev	1961	[51]
γ-solid	54.3	−218.8	1.372			
α-solid	20.6	−252.5	1.4256			

The density of liquid oxygen for a wide range of pressures can be displayed graphically or printed out as a table by an on-line app on the NIST Chemistry WebBook Fluids web page [52]. A sample calculation for $p = 0.101, 1.01$ and 10.1 MPa and $55 < T < 90 \text{ K}$ is shown in Figure 3.

Figure 3: Density of liquid oxygen for $p = 0.101, 1.01,$ and 10.1 MPa (reproduced and modified from [52].)

For additional LOX density data see also [53–56]. The density of the liquid at the triple point is $24.492 \pm 0.02 \text{ cm}^3/\text{mol}$. The density data of liquid oxygen at atmospheric pressure measured by a pycnometric float/sinker method were fitted to a polynomial regression function of the form [57]:

$$\rho = a + bx + cx^2 + dx^3 + 6x^4 + fx^5$$

where ρ is the density in g/cm^3 , T is the temperature in kelvin, $x = (1 - T/T_c)$, and $T_c =$ critical temperature ($T_c = 154.77 \text{ K}$). The coefficients in this equation are: $a = 0.487609$, $b = -0.203117$, $c = 4.624474$, $d = -9.374911$, $e = 9.517905$, $f = -3.590726$.

The density of liquid oxygen at atmospheric pressure as a function of temperature can be expressed by the following simple equation:

$$\rho = 1.248874 - 0.00481(T - 68)$$

where ρ is the density in g/cm^3 and T is the temperature in kelvin. Data for the coefficient of thermal expansion of liquid oxygen at constant pressure are listed in Table 5.

Table 5: Coefficient of thermal expansion of liquid oxygen at constant pressure, α_p .

Temperature	$1/V (dV/dT)$
K	$1/^\circ\text{C}$
90.31	3.95×10^{-3}
77.35	3.81×10^{-3}
90.00	3.95×10^{-3}
80.00	3.84×10^{-3}
70.00	3.73×10^{-3}
65.00	3.68×10^{-3}

Data source: [58, 59]

3.3.2 Density of Liquid Oxygen at Elevated Pressure

The density of liquid oxygen increases at elevated pressures. Density of LOX at up to 148 atm = 14.9 MPa is listed in Table 6 and shown in Figure 4.

The density data in Table 6 and Figure 4 above can be expressed by the equation

$$\rho = A + BP$$

where ρ is the density in g/cm^3 and P is the pressure in atm. The factors A and B are dependent on temperature and can be calculated from the following equations:

$$A = 1.5656 - 4.896 \times 10^{-3}T + 2.136 \times 10^{-6}T^2$$

$$B = (-0.53327 + 0.02824T)10^{-4}$$

where A and B are dimensionless constants and T is the temperature in kelvin.

The measurements at pressures up to 150 kg/cm^2 reported in 1960 suggested a linear dependence of density (= specific weight) of liquid oxygen with pressure; however, more accurate measurements over a wider pressure range at pressures up to 850 kg/cm^2 showed a more complex dependence of $(\partial\rho/\partial P)_T$ with pressure, as shown in Table 7 and Figure 5.

Figure 5: Density of liquid oxygen as a function of pressure up to 850 atm. (reprinted and modified from [60], with permission from © 1961 Elsevier; permission conveyed through RightsLink)

The data in Table 7 can be expressed by the following two equations:

$$\text{At } 90.26 \text{ K: } \rho = 0.7497 + 3.493 \times 10^{-4} \times P - 3.431 \times 10^{-7} \times P^2 + 0.01713 \times 10^{-8} \times P^3$$

$$\text{At } 77.31 \text{ K: } \rho = 0.8079 + 2.521 \times 10^{-4} \times P - 2.031 \times 10^{-7} \times P^2 + 0.007995 \times 10^{-8} \times P^3$$

where ρ is the density in g/cm^3 and P is the pressure in atm.

Some older data on the density of liquid oxygen as a function of temperature and pressure are shown in Figure 6.

Figure 6: Density of liquid oxygen as a function of temperature and pressure (reproduced and modified from [55])

Note: pressure indicated as an auxiliary parameter next to each curve.

One of the older publications described a pressure-volume-temperature (PVT) equation that covers the range of temperatures 153–83 K and pressures $(78.5\text{--}196) \times 10^5 \text{ N/m}^2$ [61].

The following PVT measurements were carried out by weighing a sample of pure oxygen in a stainless-steel container and condensing it into a chamber of known volume [62]. Measurements of saturated liquid density of oxygen between 67.5 and 300 K for pressures up to 7.2 MPa were compared to data reported by 5 earlier investigators and fitted to the equation:

$$\frac{\rho}{\rho_c} = 1 + A\tau^{\frac{1}{3}} + B\tau^{\frac{2}{3}} + C\tau^{\frac{9}{3}}$$

where ρ is the molar density in mol/L, ρ_c is the critical density = 13.60 mol/L, $\tau = 1 - (T/T_c)$, T is the temperature in K, T_c is the critical temperature = 154.581 K, and the constants A through C are: A = -1.523779, B = 0.844538, C = 0.204933. Figure 7 illustrates density data calculated with this equation.

Figure 7: Density of liquid oxygen at atmospheric pressure (based on data from [62])

The density of the saturated vapor phase from 68 K to the critical temperature could be expressed by a more complex equation:

$$\ln\left(\frac{\rho}{\rho_c}\right) = A\tau^{\frac{1}{3}} + B\tau^{\frac{2}{3}} + C\tau^{\frac{3}{3}} + D\tau^{\frac{4}{3}} + E\tau^{\frac{5}{3}} + F\tau^{\frac{6}{3}} + G\tau^{\frac{19}{3}}$$

where ρ is the molar vapor density in mol/L, ρ_c is the critical density = 13.60 mol/L, $\tau = 1 - (T/T_c)$, T is the temperature in K, T_c is the critical temperature = 154.581 K, and the dimensionless constants A through G are: A = -1.306760, B = -5.514156, C = 21.220071, D = -67.611241, E = 93.883538, F = -57.568463, G = -39.328162.

The following form for an equation of state (EOS) for oxygen vapor follows the more traditional format with covolume and virial coefficients [63]:

$$\frac{P}{\rho RT} = 1 + B\rho + C\rho^2 + \dots$$

where P is the pressure and ρ is the density. The temperature dependence of the second and third virial coefficients is represented by the following functions:

$$B = f(T) = b_1 + b_2 T^{-0.25} + b_3 T^{-3.5} + b_4 T^{-4.5} + b_5 T^{-5.5} \quad (1)$$

$$C = f(T) = c_1 T^{-0.25} + c_2 T^{-6} + c_3 T^{-6.75} \quad (2)$$

where T is the temperature in kelvin, $B = f(T)$ is the covolume in L/mol, and $C = f(T)$ is the repulsive force constant in (L/mol)². The coefficients for Eqs. (1) and (2) are given below:

$$b_1 = 0.143389$$

$$b_2 = -0.629863$$

$$b_3 = -0.577814 \times 10^7$$

$$b_4 = 0.695858 \times 10^9$$

$$b_5 = -0.246023 \times 10^{11}$$

$$c_1 = 0.451336 \times 10^{-2}$$

$$c_2 = 0.987169 \times 10^{11}$$

$$c_3 = -0.364928 \times 10^{13}$$

These and PVT data from 22 different sources were critically reviewed and a small set of reliable data was selected to calculate density and compressibility data for LOX, resulting in a more accurate EOS [30].

A very accurate but also very complex equation of state for LOX is given by the equation [64]:

$$P = RT\rho_M + (A_1 + A_2T + A_3T^2) + (A_4 + A_5T + A_6T^2 + A_7T^3)\rho_M + (A_8 + A_9T + A_{10}T^2)\rho_M^2 + (A_{11} + A_{12}T)\rho_M^3$$

where P is the pressure in MPa, T is temperature in kelvin, ρ_M is molar density in mol/cm³, and R is the gas constant taken as 8.3147 J mol⁻¹ K⁻¹. The molecular mass

of oxygen is taken as 31.9988 g/mol. The constants have the following numerical values:

$$\begin{aligned}
 A_1 &= -1.641561252 \times 10^3 \text{ MPa}, \\
 A_2 &= 1.147287363 \times 10^1 \text{ MPa/K}, \\
 A_3 &= -1.893991658 \times 10^{-2} \text{ MPa/K}^2, \\
 A_4 &= 1.855069328 \times 10^5 \text{ J/mol}, \\
 A_5 &= -1.163758279 \times 10^3 \text{ J mol}^{-1} \text{ K}^{-1}, \\
 A_6 &= 1.470658133 \text{ J mol}^{-1} \text{ K}^{-2}, \\
 A_7 &= 5.082303291 \times 10^{-4} \text{ J mol}^{-1} \text{ K}^{-3}, \\
 A_8 &= -6.905607063 \times 10^6 \text{ (J/mol) (cm}^3\text{/mol)}, \\
 A_9 &= 3.696268789 \times 10^4 \text{ (J/mol K) (cm}^3\text{/mol)}, \\
 A_{10} &= -3.493447874 \times 10^1 \text{ (J mol}^{-1} \text{ K}^{-2}) \text{ (cm}^3\text{/mol)}, \\
 A_{11} &= 7.817570089 \times 10^7 \text{ (J/mol) (cm}^3\text{/mol)}^2, \\
 A_{12} &= -2.981428648 \times 10^5 \text{ (J mol}^{-1} \text{ K}^{-1}) \text{ (cm}^3\text{/mol)}^2
 \end{aligned}$$

Table 8 gives examples of density values calculated with this equation in comparison to densities calculated with another equation. These density data were later used to correlate dielectric constant measurements with density of liquid oxygen.

The density of LOX being loaded into a launch vehicle must be accurately known while the loading is in progress and until the engine ignites. The density can be calculated accurately if accurate temperature measurements are available [65]. The temperature readings can be fed to a microprocessor that adjusts the LOX temperature and density while the fueling is in progress.

The density of liquid oxygen was determined by a piezometric method at 93–153 K (–120 to –180 °C) and 20.26 MPa (200 atm) [66, 67]. The lowering of the density on changing the variables was determined by its outflow from the piezometer and the quantity was measured by its volume. The lower limit of pressure in this experiment was along the saturation curve. See also reference [68].

A cubic EOS was used to model the state of LOX in a rocket engine [69].

3.3.3 Density of Gaseous Oxygen at Elevated Pressure

The second virial coefficient for cold gaseous oxygen at the boiling point of liquid oxygen was derived from velocity of sound measurements [70].

The second and third virial coefficients of oxygen (and nitrogen) were calculated for a model pair potential considering the quantum corrections and non-additive components [71]. With this help a fourth virial coefficient was determined from the experimental data on p , ρ , and T . An empirical expression, the coefficients of which were found from an analysis of tabulated data on p , ρ , and T at pressures up to 100 MPa, was used for the fourth virial coefficient. Considering the fourth virial coefficient made it

possible to more than double the size of the region of applicability of the EOS for both pure gases and mixtures. It turned out that the region of applicability of the expression obtained in many cases (helium, neon, nitrogen) appreciably exceeded 100 MPa, but this EOS has certain limitations.

3.3.4 Density of Solid Oxygen

The density of frozen O₂ at 16 K is $\rho = 1.54 \text{ g/cm}^3$ and the refractive index at 543 nm is 1.322 [72]. For solid oxygen, if it should accidentally freeze in a propellant line, it is important to know if it expands on freezing like water and ruptures the lines or if it continues to contract as it cools off [73]. There are small volume changes associated with the phase changes of solid oxygen.

Table 9: Measured and interpolated molar volumes and densities of solid oxygen.

Data source: [36]

The density of the various phases of solid oxygen are summarized in Table 9 and illustrated in Figure 8.

3.4 Compressibility and Velocity of Sound of Liquid Oxygen

3.4.1 Compressibility of Liquid Oxygen

Data for the isothermal compressibility β_T and adiabatic compressibility β_S of liquid oxygen are listed in Table 10.

During pumping from the propellant tank, passage through the oxidizer pump and into the injector, the physical properties of LOX that are dependent on pressure will change slightly and will no longer be identical with the properties of LOX in the propellant tank. Calculations using the examples of LOX and RP-1 showed

Data source: [59, 74, 75]

that changes of density and temperature of LOX after adiabatic compression are not all that large but may have to be taken into consideration when designing a propellant feed system and injector orifices [76]. For instance, the temperature of LOX increased by 0.28 K for every 6.8 atm (100 psi) of pressure increase during adiabatic compression.

The adiabatic and isothermal compressibilities of LOX were calculated from thermodynamic data using two different methods [77]. As shown in Figure 9, the isothermal data obtained in this way agreed well with those measured by Chao [75] and Liepmann [78].

Figure 9: Isothermal compressibility of liquid oxygen (republished and modified from [77], with permission of © 1960 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

3.4.2 Velocity of Sound of Liquid Oxygen

Velocity of sound data of liquid oxygen are summarized in Table 11 and 12. The velocity of sound can be used to calculate the compressibility of liquid oxygen.

Figure 10 shows the velocity of sound in liquid oxygen at 539.6 kHz as a function of temperature [79]. Additional velocity of sound in liquid oxygen data are available also in comparison to liquid nitrogen [80] and for cold gaseous oxygen at the boiling point of liquid oxygen [70].

The velocity of sound in liquid oxygen as a function of temperature and pressure can be displayed graphically or printed out as a table by an on-line interactive application on the NIST Chemistry WebBook Fluids web site. An example for $p = 0.101, 1.01, \text{ and } 10.1 \text{ MPa}$ and $55 < T < 90$ is shown in Figure 11.

The transfer of LOX from a ground storage vessel to a flight tank and from a flight tank to a rocket engine generally requires the use of a pressurizing gas like helium or

Figure 11: Velocity of sound in liquid oxygen for $p = 0.101, 1.01,$ and 10.1 MPa (based on data from [10])

nitrogen at pressures up to 20.6 MPa (3000 psi). If nitrogen instead of helium is used as the pressurant gas, the condensation of gaseous nitrogen into the cryogenic liquid, combined with high miscibility, results in contamination of the LOX, which has a deleterious effect on engine performance. It has been proposed to monitor the liquid oxygen/liquid nitrogen (LOX/LN₂) contamination through sound velocity measurements. Therefore, the sound velocity of LOX/LN₂ mixtures was measured under controlled conditions for later use in a practical LOX contamination monitor [81, 82]. The measurements, performed by the pulse-echo technique on several LOX/LN₂ compositions, revealed a slight deviation from a linear dependence of the sound velocity upon the mol fraction of LN₂. The results for pure LOX and pure LN₂ at 77.35 K (−195.8 °C) and 1 atm pressure were $1008.5 \pm 0.25\%$ m/s ($1009.05 \pm 0.25\%$ m/s) and $852.8 \pm 0.32\%$ m/s, respectively, and these results were compared to measurements reported in the literature. The relationship between sound velocity c and LN₂ content M is:

$$c = 1009.05 - 1.8275M + 0.0026507M^2$$

where c is the velocity of sound in m/s and M is the nitrogen concentration in mol-%. Measurement of sound velocity should prove an effective means for monitoring the contamination of LOX by LN₂.

Velocities of hypersonic (3–5 GHz) waves in liquid oxygen have been determined by thermal Brillouin scattering techniques [83]. The incident radiation ($\lambda = 5145 \text{ \AA}$) was obtained from a stabilized single-mode argon-ion laser, and the scattered radiation was analyzed at 90° with a piezoelectrically-scanned Fabry-Perot spectrometer. Mea-

surements covered the temperature range from the triple point (54.35 K) to the normal boiling point (90.18 K), and in this range the velocities were observed to decrease linearly with increasing temperature from 1193 to 909 m/s. These results were compared with ultrasonic (1.2 MHz) velocities as measured by van Itterbeek and van Dael at temperatures above 61 K, and no dispersion effects were evident at least up to 3.6 GHz. See also reference [84].

3.5 Vapor Pressure of Oxygen

3.5.1 Vapor Pressure of Liquid Oxygen

The vapor pressure of liquid oxygen is listed in Table 13.

Table 13: Vapor pressure of liquid oxygen.

Temperature K	Vapor pressure		
	mmHg	atm	psia

150	31631	41.620	611.6

Data source: [33]

The original vapor pressure equation for the temperature range between the triple point and the critical point as derived by Brower and Thodos [29] was:

$$\log P = 13.4275 - 469.150/T - 2.7391 \log T + 0.1155P/T^2$$

where P is the vapor pressure in mmHg and T is the temperature in kelvin. This is an unusual transcendental equation that includes the variable P on both sides of the equal sign. The equation should be solved so P is only on one side of the equal sign and T is only on the other side of the equal sign.

$$\log P - 0.1155P/T^2 = 13.4275 - 469.150/T - 2.7391 \log T$$

The average deviation of this equation is $\pm 0.43\%$. This is also called the Frost-Kalkwarf vapor pressure equation and was based on 259 data points.

The vapor pressure of liquid oxygen can be calculated from the Antoine equation

$$\log_{10}(P) = A - \left(\frac{B}{(T + C)} \right)$$

where P is the vapor pressure in bar and T is the temperature in kelvin [27]. The Antoine equation parameters are given in Table 14 for two different temperature ranges.

Table 14: Antoine equation parameters for vapor pressure of liquid oxygen.

Temperature range, K	A	B	C
54.36–100.16	3.85845	325.675	–5.667
54.36–154.33	3.9523	340.024	–4.144

Data source: [29] as cited by [27]

The vapor pressure of liquid oxygen as a function of temperature can be displayed graphically or printed out as a table by an on-line interactive app on the NIST Chemistry WebBook Fluids web site. An example for $55 < T < 120$ is shown in Figure 12.

Data compilations and evaluations by NIST [30] reference the data by Wagner, Ewers, and Penttermann [63, 85] as the most reliable source of vapor pressure and other data as of 1991:

$$\ln \pi = \left(\frac{T_c}{T} \right) \left(n_1 \tau + n_2 \tau^{\frac{3}{2}} + n_3 \tau^3 + n_4 \tau^7 + n_5 \tau^9 \right)$$

where π is the reduced pressure P/P_c , P is the vapor pressure in MPa, P_c is the critical pressure = 5.0430 MPa, T_c is the critical temperature = 154.581 K, T is the temperature

Figure 12: Vapor pressure of liquid oxygen (based on data from [52])

in kelvin, and $\tau = (T_c - T)/T_c$. The dimensionless coefficients n_1 through n_5 are as follows:

$$n_1 = -6.043938,$$

$$n_2 = 1.175627,$$

$$n_3 = -0.994086,$$

$$n_4 = -3.456781,$$

$$n_5 = 3.361499.$$

See also reference [86]. Alternatively, the following two equations can be used to calculate the vapor pressure of liquid oxygen between 66 and 90 K and between 90 and 110 K [87]:

$$\log p = 7.86224 - 408.740/T - 0.0049832 T \quad (66 \text{ K} < T < 90 \text{ K})$$

$$\log p = 6.92979 - 365.186/T \quad (90 \text{ K} < T < 110 \text{ K})$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin.

3.5.2 Vapor Pressure of Solid Oxygen

The vapor pressure of sublimation of solid oxygen is very small and difficult to measure, but it appears that it plays a role in the accumulation of oxygen on very cold extraterrestrial bodies where it would be a welcome resource for ISRU for future spacefarers.

It has been considered to store oxygen in the solid instead of the liquid form to minimize evaporation losses. In this case the vapor pressure of solid oxygen would determine the rate of loss of oxygen by sublimation [88–90].

Frozen oxygen would be a potential constituent of cryogenic solid propellants and therefore its physical properties must be known before such propellants can be formulated. Frozen oxygen is a constituent of slush oxygen. The transition of frozen oxygen to a metallic state at very high pressures changes its properties dramatically.

3.6 Viscosity of Oxygen

Instead of viscosity, sometimes the fluidity is given in its place. Fluidity is the reciprocal of viscosity. One must differentiate between dynamic (= absolute) viscosity and kinematic viscosity. The SI physical unit of *dynamic viscosity* is Pascal-second ($\text{Pa} \cdot \text{s}$), (equivalent to $(\text{N} \cdot \text{s})/\text{m}^2$, or $\text{kg m}^{-1} \cdot \text{s}^{-1}$). The cgs physical unit for dynamic viscosity is the *poise*, abbreviated as P or Ps, most often used as centipoise, abbreviated as cP or cPs. We prefer the abbreviation Ps because P is most often already used as the symbol for pressure.

$$1 \text{ P} = 1 \text{ Ps} = 0.1 \text{ Pa} \cdot \text{s}$$

$$1 \text{ cP} = 1 \text{ cPs} = 1 \text{ mPa} \cdot \text{s} = 0.001 \text{ Pa} \cdot \text{s}.$$

The SI unit of *kinematic viscosity* is m^2/s . The cgs physical unit for *kinematic viscosity* is the stokes, abbreviated as St. It is sometimes expressed in terms of centistokes (cSt).

$$1 \text{ St} = 1 \frac{\text{cm}^2}{\text{s}} = 10^{-4} \frac{\text{m}^2}{\text{s}}$$

$$1 \text{ cSt} = 1 \frac{\text{mm}^2}{\text{s}} = 10^{-6} \frac{\text{m}^2}{\text{s}}.$$

3.6.1 Viscosity of Gaseous Oxygen

Since dioxygen is a small diatomic molecule the temperature dependence of its viscosity in the dilute gas state or zero-density limit can be well represented by expressions derived from kinetic theory. The viscosity can be derived from an equation that contains the absolute temperature T , the molar mass M , Boltzmann constant k , Avogadro number N_A and the collision integral. Viscosity data for gaseous oxygen along the saturation line and for temperatures from 70 to 850 K and pressures up to 100 MPa calculated from that equation were included in a table (Table 3) of the following reference but are not shown here in full because it would take too much space [91]. An abbreviated version of Table 3 from Laesecke et al. [91] is shown in Table 15 that includes both viscosity and thermal conductivity data.

Table 15: Viscosity and thermal conductivity of oxygen along the saturation line.

Temperature K	Pressure MPa	Viscosity, liquid $\mu\text{Pa s}$	Viscosity, gas $\mu\text{Pa s}$	Thermal conduc- tivity, liquid $\text{mW m}^{-1} \text{K}^{-1}$	Thermal conduc- tivity, gas $\text{mW m}^{-1} \text{K}^{-1}$

Data source: [91]

The viscosity and thermal conductivity data in Table 15 for gases above the boiling liquid at the saturation pressure differ substantially from viscosity and thermal conductivity data for gases at atmospheric pressure, shown in other parts of this chapter.

3.6.2 Viscosity of Liquid Oxygen

The dynamic viscosity of liquid oxygen is summarized in Table 16.

The viscosity of liquid oxygen at atmospheric pressure in the range from 68 to 90 K is shown in Figure 13 where the open circles and the $\times$ symbols indicate van Itterbeek, Zink, and van Paemel [92] data and the other symbols indicate data from Rudenko and

Table 16: Dynamic viscosity of liquid oxygen η .

Temperature K	Dynamic viscosity η	
	$\mu\text{Pa s}$	Ps
68.70	379.3	379.3×10^{-5}
71.40	336.9	336.9×10^{-5}

90.25	187.9	187.9×10^{-5}

Data source: Gmelin Handbook 1935

Figure 13: Viscosity of liquid oxygen (reprinted and modified from [92], with permission from © 1962 Elsevier; permission conveyed through RightsLink)

Shubnikov 1934 [93], but the authors failed to identify the units of measurement for η on the ordinate scale. We assume the units of the ordinate scale are Poise (1 Poise = 0.1 N s m^{-2}) multiplied times 10^5 , reference [92].

Viscosity of liquid oxygen was calculated from the residual viscosity expressed by a complicated equation that contained terms for reduced density and parameters derived from a set of critically evaluated literature data. Viscosity data for liquid oxygen from 70 to 154 K along the saturation line calculated from that equation are included in Table 15 (this is based on Table 3 as shown in reference [91]). A shortened version of that table is shown.

Equations for the viscosity and thermal conductivity of oxygen derived from several dozen of carefully evaluated literature references were developed and they were valid over all liquid and vapor states [94]. For instance, the viscosity of oxygen at 100 K for a liquid with a density of 35.0 mol/L was calculated as $172.136 \mu\text{Pa s}$ and the viscosity of oxygen at the critical point at 154.6 K with a density of 13.6 mol/L was calculated as $24.7898 \mu\text{Pa s}$.

The viscosity of liquid oxygen as a function of temperature can be displayed by an on-line interactive app on the NIST Chemistry WebBook Fluids web site. An example for saturated liquid/gas two-phase region and $55 < T < 120$ is shown in Figure 14.

Figure 14: Dynamic viscosity of saturated liquid and gaseous oxygen (based on data from [52])

Absolute dynamic viscosity of subcooled liquid oxygen from 0.15 to 1.0 MPa and from 55.20 to 90.19 K was measured using a pressurized gravitational capillary (PGC) viscometer specifically designed for subcooled liquefied gases [95]. Measurements of the dependency of viscosity on pressure between 0.15 and 1 MPa showed that there is very little variation of viscosity with pressure in this range. Selected viscosity and density data are summarized in Table 17.

Table 17: Dynamic (=absolute) viscosity and density of subcooled liquid oxygen at different pressures.

Temperature K	Pressure kPa	Viscosity $\mu\text{Pa s}$	Density kg/m^3
55.000	152.3	799.3	1303.9
90.187	153.7	196.7	1140.7

Data source: [95]

The slope of the pressure curves $\partial\mu/\partial P$ decreased from 0.014 to 0.0044 ns as the temperature was increased from 55 to 90 K. The natural logarithm of viscosity as a function of reciprocal absolute temperature can be displayed as a straight line in an Arrhenius-type graph (Figure 15). Only the lowest pressure (0.15 MPa) data points are shown in this graph because they all overlap. See also [96, 97].

Figure 15: Absolute dynamic viscosity of subcooled liquid oxygen at 150 kPa (reprinted and modified from [95], with permission from © 2008 Elsevier; permission conveyed through RightsLink)

3.7 Surface Tension of Oxygen

The surface tension of liquid oxygen as listed in Table 18 is almost double that of liquid nitrogen ($\sigma_{\text{O}_2} = 16.51 \text{ dyn/cm}$ and $\sigma_{\text{N}_2} = 8.94 \text{ dyn/cm}$ at $T = 77 \text{ K}$, $\sigma_{\text{O}_2} = 16.25 \text{ dyn/cm}$, and $\sigma_{\text{N}_2} = 8.72 \text{ dyn/cm}$ at $T = 78 \text{ K}$).

Conversion: $1 \text{ dyn/cm} = 10^{-3} \text{ N/m}$

The surface tension of liquid oxygen as a function of temperature can be displayed by an on-line interactive app on the NIST Chemistry WebBook Fluids web site [52]. An example for saturated liquid/gas two-phase region and $55 < T < 120$ is shown in Figure 16.

Using a capillary method and a split-type superconducting magnet, the surface tension of liquid oxygen has been measured in magnetic fields up to 5 T at 65.3 and 77.1 K [98]. It was found that the dependence of surface tension on magnetic field strength is so small that it cannot be the main cause of the shape deformation of the meniscus.

Table 18: Surface tension of liquid oxygen.

Temperature		Surface tension, σ	Authors	Year	References
°C	K	dyn/cm			
-182.7	90.5	13.2 ± 0.2	Jenkins and Dipaolo	1956	[50]
-203.2	70	18.3	Baly and Donnan	1902	[49]

-183.2	95	13.2	Baly and Donnan	1902	[49]

**Figure 16:** Surface tension of saturated liquid oxygen (modified from [52])

The surface tension of oxygen at the liquid-vapor interface was calculated for the temperature range of 60–90 K using molecular dynamic simulations and could be reproduced within 1.0% error of experimental values for most of the temperatures studied, as summarized in Table 19 and illustrated in Figure 17.

The experimental data points are from reference [100], which in turn lists four older sources of surface tension data ranging from 1902 to 1970 [101–104].

The surface tension of LOX as a function of temperature can be calculated from

$$\sigma = 38.612652\tau^{1.228}$$

where σ is the surface tension in dyn/cm, $\tau = 1 - T/T_c$, T_c is the critical temperature in kelvin and T is the temperature in kelvin.

Table 19: Experimental and molecular dynamic theoretical results for surface tension of oxygen.

Temperature K	Surface tension	
	Experimental results $\sigma \times 10^2$, N/m	Molecular dynamics theoretical results $\sigma \times 10^2$, N/m
60	2.1122	2.1204
65	1.9759	1.9850

75	1.7086	1.6974
80	1.5777	1.5487
85	1.4489	1.4378
90	1.3221	1.2986

Source of data: [99]

Figure 17: Surface tension of oxygen at the liquid-vapor interface (republished and modified from [99], with permission of © 2006 American Institute of Physics; permission conveyed through Copyright Clearance Center, Inc.)

Quite often LOX is pressurized with helium and a little helium will dissolve in LOX. The small amount of helium dissolved in LOX has not much of an effect on the surface tension of LOX [105, 106].

An older source [107] of surface tension of LOX gives the temperature dependence as a linear equation as:

$$\sigma = 36.64 - 0.262 T$$

where σ is the surface tension in $\text{N/m} \times 10^3$, and T is the temperature in kelvin. This function is illustrated in Figure 18 in comparison to experimental data from various sources. The purity of the oxygen, which was prepared by decomposition of potassium permanganate, was better than 99.9 mass %.

Figure 18: Surface tension of liquid oxygen (reproduced and modified from [107])

3.8 Thermal Conductivity of Oxygen

3.8.1 Thermal Conductivity of Gaseous Oxygen

Since dioxygen is a small diatomic molecule, the temperature dependence of its thermal conductivity in the dilute gas state or zero-density limit can be well represented by expressions derived from kinetic theory. The thermal conductivity can be derived from an equation that contains the absolute temperature T , the molar mass M , universal gas constant R , isochoric heat capacity, and the viscosity. There are substantially fewer reports on thermal conductivity of gaseous oxygen in the literature than there are publications on viscosity. Fourteen sets of original data from the literature were evaluated to obtain the coefficients for a very complicated thermal conductivity equation. Thermal conductivity data for gaseous oxygen along the saturation line and for temperatures from 70 to 850 K and pressures up to 100 MPa calculated from that equation were included a table (Table 3) of the following reference but are not shown here because it would take too much space [91].

A shortened version of that table was presented in the section “Viscosity of Gaseous Oxygen”.

The measured thermal conductivity of gaseous oxygen in Table 20 is given in several units and compared to numbers calculated from a curve-fit polynomial equation.

Table 20: Thermal conductivity of gaseous oxygen, measured and smoothed values.

380	8.033	33.61	78.03	326.5	32.65

Data source: [108]

The measured data from Johnston and Grilly [108] can be closely represented by a polynomial equation [109]:

$$\lambda = -0.7816 + 23.8 \times 10^{-2} \times T - 0.8939 \times 10^{-4} \times T^2 + 2.324 \times 10^{-8} \times T^3$$

where λ is the thermal conductivity in $\mu\text{cal s}^{-1} \text{cm}^{-1} \text{K}^{-1}$ and T is the absolute temperature in kelvin.

The thermal conductivity of liquid and gaseous oxygen was measured at temperatures between 80 and 200 K at pressures between 1 and 130 atm using a vertical coaxial cylinder method and the results were compared with those of other authors [110, 111]. The thermal conductivity of gaseous oxygen as a function of temperature and pressure is shown in Figure 19 and 20. The shape of a graph displaying the thermal conductivity as a function of temperature and pressure (Figure 20) is very similar to one displaying density as a function of temperature and pressure.

Figure 20: Thermal conductivity of gaseous oxygen as a function of pressure and temperature. (reproduced and modified from [110], with permission granted by © 1955 IOP Publishing. All rights reserved)

3.8.2 Thermal Conductivity of Liquid Oxygen

Investigators measuring the thermal conductivity of LOX and other cryogenic fluids have utilized thin layers of liquids and small temperature differences. One investigator designed an apparatus which used a liquid layer only 0.4 mm (0.0156 in.) thick and a temperature difference of 0.5 K (1 °F) and obtained fairly accurate data; however, it has been found that it becomes exceedingly difficult to accurately measure the temperature difference with very thin layers of liquids. Other investigators constructed an apparatus using a hot wire technique with a liquid layer of 5 mm thickness and temperature difference of the order of 1 °C or less. In order to minimize the effect of convection on thermal conductivity measurements on fluids near the critical region, it is necessary that the fluid film through which the heat is transported should be as thin as possible. Thus, the parallel plate method, or the coaxial cylinder method is to be preferred to the hot wire method. The thermal conductivity of liquid oxygen between 66.1 and 82.1 K (–207 and –191 °C) has been determined as described in reference [112]. In this method the liquid layer 1.2 cm thick was enclosed between two parallel copper disks, the heat flow being measured from the upper to the lower disk. The temperature difference was measured by differential thermoelements located in the liquid layer. The values of thermal conductivity of LOX between 93.5 and 91.1 K (–179.6 and –182 °C) have been calculated from the heat transfer data using Nusselt's equation and are given in Table 21. The points are fairly scattered as is usually the case with heat transfer data, but they compare favorably with the extrapolated data of Hammann [112] who mea-

Table 21: Thermal conductivity of liquid oxygen.

Temperature		Coefficient of heat transfer		Thermal conductivity	
K	°C	$\text{W m}^{-2} \text{K}^{-1}$	$\text{cal } ^\circ\text{C}^{-1} \text{cm}^{-2} \text{s}^{-1}$	$\text{W m}^{-1} \text{K}^{-1}$	$\text{cal } ^\circ\text{C}^{-1} \text{cm}^{-1} \text{s}^{-1}$
77	-196			0.186	$4.44 \times 10^{-4} *$
91.1	-182.0	7942	1897×10^{-4}	0.224	5.36×10^{-4}
91.8	-181.3	5112	1221×10^{-4}	0.212	5.06×10^{-4}
92.1	-181.0	3961	946×10^{-4}	0.194	4.64×10^{-4}
92.4	-180.7	3952	944×10^{-4}	0.210	5.02×10^{-4}
93.3	-179.8	3856	921×10^{-4}	0.220	5.27×10^{-4}
93.5	-179.6	3768	900×10^{-4}	0.223	5.32×10^{-4}

Data source: [113], except * which is from [114] and [115].

sured at 73 K (-200°C) $\lambda = 4.98 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} ^\circ\text{C}^{-1}$. The mean value of the thermal conductivity between 95.5 and 91.1 K (-177.6 and -182°C) is $5.05 \times 10^{-4} \text{ cal s}^{-1} \text{ cm}^{-1} ^\circ\text{C}^{-1}$.

The thermal conductivity of liquid oxygen as a function of temperature can be displayed graphically or printed out as a table by an on-line interactive app on the NIST Chemistry WebBook Fluids web site. An example for thermal conductivity in the saturated liquid/gas two-phase region for $55 < T < 120$ is shown in Figure 21.

**Figure 21:** Thermal conductivity of saturated liquid oxygen (reproduced and modified from [52])

Equations for the thermal conductivity of oxygen derived from several dozen carefully evaluated literature references were developed and they were valid over all liquid and vapor states, and a simplified cross-over equation was used to model the behavior of the critical enhancement for thermal conductivity [94]. For instance, the thermal

conductivity of oxygen at 100 K for a liquid with a density of 35.0 mol/L was calculated as $146.044 \text{ mW m}^{-1} \text{ K}^{-1}$ and the viscosity of oxygen at the critical point at 154.6 K with a density of 13.6 mol/L was calculated as $377.476 \text{ mW m}^{-1} \text{ K}^{-1}$.

The thermal conductivity of liquid oxygen below 80 K and at pressures up to 1 MPa was measured using a horizontal, guarded, flat-plate calorimeter [116, 117]. Raw data are summarized in Table 22.

Table 22: Thermal conductivity of subcooled liquid oxygen.

Data source: [117]

The thermal conductivity of subcooled liquid oxygen as a function of temperature and pressure is shown in Figure 22. In the range from 0.1 to 1 MPa, thermal conductivity of liquid oxygen is not very sensitive to pressure, and the curves virtually fall on top of each other.

Thermal conductivity data for liquid oxygen from 70 to 154 K along the saturation line calculated are included in Tables 3 and 5 of reference [91] shown in the section “Viscosity of Gaseous Oxygen”. See also [96, 97, 118].

The thermal conductivity of gaseous oxygen was investigated by a heated wire method at temperatures from 83 to 298 K (−190 to +25 °C) and at constant pressures of 100 and 60 atm [119, 120]. In this apparatus, heat was supplied by an electrically

Figure 22: Thermal conductivity of liquid oxygen as a function of temperature and pressure (reprinted and modified from [117], with permission from © 2005 Elsevier; permission conveyed through RightsLink)

heated wire and flowed in a radial direction to the wall of a capillary across a gap of 0.21 mm. From a logarithmic correlation of the experimental results, two different equations were derived:

$$\lambda = \lambda_0 + 4.30 \times 10^{-8} \times \rho^{2.11}$$

for ρ greater than 825 kg/m³ and

$$\lambda = \lambda_0 + 1.246 \times 10^{-5} \times \rho^{1.24}$$

for ρ between 50 to 535 kg/m³, where λ and λ_0 are the coefficients of thermal conductivity of liquid and gaseous oxygen in kcal m⁻¹ h⁻¹ °C⁻¹, respectively, ρ is the specific gravity of oxygen in kg/m³. By means of these two formulas, the coefficients of thermal conductivity of oxygen can be calculated for pressures from 1 to 100 atm and temperatures from 73 to 313 K (−200 to +40 °C). See also reference [121].

The thermal conductivity of oxygen has been measured at temperatures from 77 to 310 K with pressures to 70 MPa and densities from 0 to 40 mol/L [122]. The measurements covered the physical states of the dilute gas, the dense gas, the region near critical, compressed liquid states, metastable liquid states at conditions just below saturation, and vapor states at temperatures below critical and pressures less than the vapor pressure. The results were analyzed in conventional terms to develop a mathematical

description of the thermal conductivity surface. The thermal conductivity surface was represented with an equation that was based in part on an existing correlation of the dilute gas. The new thermal conductivity surface revealed that the critical enhancement, or an anomalous increase in thermal conductivity, persisted to reduced temperatures that were quite high, approximately $2T_c$. Figure 5 of that publication attempts to illustrate the thermal conductivity as a function of density and temperature, but it is very difficult to extract specific data from that graph. The deviation in the curve for 159 K reveals the anomalies as the system goes through the critical point.

Equations for the transport properties in terms of pressure and temperature, so-called transport EOS, are useful design tools. The surfaces of transport properties and density as a function of pressure and temperature reveal similarities, which become even more evident when the residual transport property as a function of pressure and temperature is considered. Based on these similarities, a cubic transport EOS has been developed for the residual thermal conductivity of oxygen, which is only a little less accurate than the already established virial transport EOS for oxygen [123]. It is, however, much simpler and needs only a few parameters. The accuracy is still good enough for practical applications.

3.9 Heat Transfer Coefficient of Liquid Oxygen

When measuring the boiling heat transfer to liquid oxygen flowing in tubes in the range of nucleate and film boiling, it was observed that the coefficient of heat transfer was quite dependent on surface conditions, the type of metal and the diameter of the tubes [124, 125]. The results are illustrated in Figure 23.

The operating pressure of LOX rocket engines has been steadily increasing over the decades, gradually approaching critical point conditions. Therefore, heat transfer properties of LOX in the proximity of the critical point had to be measured [126, 127]. Table 23 contains a small portion of the data in the range of nucleate boiling.

A very thorough compilation and critical evaluation of heat transfer data in liquid oxygen (also containing some liquid hydrogen data) was published in reference [129]. This publication compared the data obtained by eight other sources in the regime of nucleate as well as film boiling. The experimental data were in good agreement with the equation proposed by Kutateladze [130].

Propellant evaporation is a criterion for rocket engine design and experimental performance evaluation and heat transfer rates have been measured with various propellant combinations and compared to model predictions [131, 132].

Bipropellant rocket engines are usually regeneratively cooled with the fuel instead of the oxidizer. Just in case design changes require an engine to be cooled with oxidizer (or with both oxidizer and fuel), the heat transfer coefficient at supercritical temperature conditions has been examined [133]. A bulk property Nusselt number was modi-

fied by bulk-to-wall temperature property ratios to give the correlation equation. Heat transfer coefficient data were obtained using electrically heated steel tubes at supercritical pressure levels 6.2–34.4 MPa (900–5000 psia) and bulk temperatures ranging from subcritical to supercritical (105–278 K = 190–500 °R) with wall temperatures up to 1000 K (1800 °R).

The heat transfer in boiling liquid oxygen in the temperature range 79–120 K (–194 to –153 °C) at pressures of 0.025–1.08 MPa was experimentally investigated and an empirical dependence of the heat-transfer coefficient on thermal flux density and pressure was derived [134]. See also [135, 136].

3.10 Critical Constants of Liquid Oxygen

The critical constants of oxygen compiled from several literature sources are summarized in Table 24.

Table 24: Critical constants of oxygen.

3.11 Solubility, Miscibility, Solutions of Liquid Oxygen

3.11.1 Helium Dissolution

Henry's Law is used to describe the relationship between the concentration of a dissolved gas in a liquid with the pressure of the fluid and is usually expressed as:

$$c = f(P, T)$$

The solubility of helium pressurant gas in liquid oxygen is summarized in Table 25.

The solubility of helium in liquid oxygen, liquid hydrogen, and liquid methane was described by empirical correlations derived from published experimental data

Table 25: Solubility of helium pressurant gas in liquid oxygen.

Pressure		Liquid composition, mol-% helium.				
MPa	psia	143 K	128 K	113 K	93 K	77 K
1.72	250			0.27	0.14	0.04
3.45	500		0.86	0.74	0.33	0.14
5.17	750	1.80	1.59	1.13	0.53	0.20
6.89	1000	3.30	2.37	1.54	0.68	0.25
8.62	1250	4.61	3.14	1.95	0.83	0.32
10.3	1500	5.98	3.84	2.32	0.99	0.36
11.9	1750	7.26	4.46	2.67	1.14	0.43
13.8	2000	8.60	5.08	3.02	1.27	0.48

Data source: [137]

for the mol fraction of these pressurant gases in the liquid phase as a function of temperature and pressure [138]. The correlations were developed to yield accurate estimates of the mol fraction of the pressurant gas in cryogenic liquids at temperature and pressures of interest to rocket propulsion engineers. The helium solubility correlations were of the form

$$\chi = p^* \exp(a + bp^*)$$

where χ is the mol fraction solubility of the solute (helium) in the solvent liquid, p^* is a dimensionless pressure defined as $p^* = (P - P_0)/P_{\text{REF}}$, where P is the total pressure (from the pressurant gas and the vapor pressure of the liquid), P_0 is the saturated vapor pressure of the pure liquid solvent at temperature T , P_{REF} is a reference pressure defined as equal to 1 MPa, and a and b are empirically determined, temperature-dependent functions. For $b = 0$, the equation assumes the form of Henry's law. In a graph showing the mol fraction $\ln(\chi/p^*)$ as a function of pressure for 4 different temperatures between 67.5 and 113 K, the curves are linear and almost level, indicating minimum dependence of χ on pressure. A graph showing the mol fraction $\ln(\chi/p^*)$ as a function of temperature showed an almost linear increase of $\ln(\chi/p^*)$ with temperature. More specifically, the equation for the temperature dependence of χ based on empirical data becomes

$$\chi = p^* \exp(-13.82 + 0.0934 \times T/\text{K} - 0.00021 \times T^2/\text{K}^2)$$

where the terms in the parentheses need to be divided by kelvin and kelvin² to make them dimensionless. The helium mol fraction solubility in liquid oxygen is less than 0.3% in typical propulsion system applications, and the times to reach equilibrium are very long in the absence of active mixing. Considering as an example a tank at the normal boiling point temperature of liquid oxygen (90.2 K) and a total pressure of 1.72 MPa (250 psia, $p^* = 1.62$) the equilibrium mol fraction solubility is $x_{\text{He}} = 0.13 \pm 0.014\%$.

Even though the proposed operating conditions for higher pressure-fed engines are not likely to exceed 2.24 MPa (325 psia), there is still a significant amount of helium that can be dissolved into the liquid oxygen. While there are no data suggesting that the surface tension properties of the liquid oxygen will be significantly altered by this dissolved helium content, this remains to be verified. The solubility of helium in LOX is very low [139].

3.11.2 Solubility of Contaminants in LOX

Contaminants that are introduced from the air before it is liquefied and separated are carried over into the finished product and may eventually accumulate in the tank if the oxygen continues to boil off. The most abundant contaminant in ambient air is carbon dioxide. Frozen carbon dioxide in liquid oxygen might clog filters, valves, and injector orifices. Some contaminants may be introduced by venting LOX tanks to air and inadvertently allowing ambient air to enter the vessel. In addition to hydrocarbons introduced from the surrounding air, hydrocarbons may be produced from decomposition of the lubricants in the compressors that compress ambient air to later cool, expand and liquefy it. Accumulation of contaminants in LOX is a significant safety hazard and that is why the solubility of contaminants is described in some detail in this chapter. Mixtures of methane and LOX have been proposed as monopropellants (see *Encyclopedia of Monopropellants*), and therefore the miscibility of the two chemicals must be known. Mixtures of nitrous oxide and LOX have been proposed as oxidizers for bipropellants and hybrid propellants.

3.11.2.1 Solubility of Hydrocarbons in LOX

Infrared spectroscopy can be used to determine the concentrations and solubility of contaminants in LOX [140]. The solubilities of several potential contaminants are listed in Tables 26 through 29.

Table 26: Solubility of contaminants in LOX at 90 K.

Compound	Mol fraction $\times 10^6$

C ₃ H ₆	83.3	-2.64
C ₃ H ₆	86.8	-2.21
C ₃ H ₆	87.4	-2.18

Data source: [142].

The high solubility of ethylene is a real surprise [141]. Solubility data for ethane, ethylene, and propylene at lower temperatures (below 90 K) are listed in Table 27.

Liquid methane was found to form clear homogeneous solutions with LOX at 90 K (-183 °C) over the whole composition range from 0 to 100% oxygen [143]. The solutions were colorless on the methane-rich side and gradually approached the color of LOX on the oxygen-rich side. Cooling to the temperature of liquid nitrogen, 77 K, however, caused solid methane to separate in mixtures containing over 50 mass-% methane. Other investigators noted that the solubility of solid methane in LOX between 69 and 74 K (-204 and -199 °C) was limited. They found that at 74 K the saturation limit of methane in LOX was 49.35 mass-% CH₄. **Warning:** mixtures of LOX and methane are potentially **detonable**, see Section 11.8.1, Cap Sensitivity of Liquid Oxygen, and 11.9, Explosive Yield of Liquid Oxygen/Fuel Mixtures.

The mol fraction χ of methane in its saturated solutions in liquid nitrogen between 70 and 79 K and in liquid oxygen between 69 and 74 K can be expressed by the equations

$$\log \chi = 1.36576 - 120.48/T$$

for nitrogen and

$$\log \chi = 0.97986 - 85.822/T$$

for oxygen where T is the temperature in kelvin [144].

Measurements of the distribution of methane between the liquid and vapor phases of oxygen at very low concentrations of methane (~1000 ppm of CH₄) over the temperature range between 93 and 107 K were done under conditions where the

highest concentration of methane in any phase was far below the lower flammable and explosive limits for the system. Average values of the equilibrium distribution constants for methane in oxygen between 93 and 107 K were 2.8–3.35 [145].

Data for the solubility of solid acetylene and carbon dioxide in liquid oxygen and liquid nitrogen are listed in Table 28. Similar data were reported for solubility of ethylene and propylene in liquid nitrogen and liquid oxygen as shown in Table 29. See also reference [146].

Table 28: Solubility of solid acetylene and carbon dioxide in liquid oxygen and liquid nitrogen.

Contaminant	Solvent	Temperature, K	Concentration, mol fraction $\times 10^6$
Acetylene	Liquid oxygen	65.1	0.641
Acetylene	Liquid oxygen	78.9	2.04
Acetylene	Liquid oxygen	98.0	10.85
Acetylene	Liquid nitrogen	65.0	0.791
Acetylene	Liquid nitrogen	79.4	2.72
Acetylene	Liquid nitrogen	95.0	19.95
Carbon dioxide	Liquid oxygen	67.0	1.77
Carbon dioxide	Liquid oxygen	78.4	2.91
Carbon dioxide	Liquid oxygen	98	5.61
Carbon dioxide	Liquid nitrogen	67.0	2.21
Carbon dioxide	Liquid nitrogen	78.4	3.47
Carbon dioxide	Liquid nitrogen	98	7.26

Data source: [147].

Propylene	Liquid oxygen	80.6	0.0282
Propylene	Liquid oxygen	86.5	0.385
Propylene	Liquid nitrogen	67	0.0017
Propylene	Liquid nitrogen	83	0.072

Data source: [148].

The solubilities of solid C_2H_2 and CO_2 in liquid oxygen and liquid nitrogen and their mixtures at sea-level pressure and at temperatures from 77.4 to 90.0 K can be calculated by the linear relations

$$\log \chi = -(59.78/T) - 4.56494$$

for C_2H_2 and

$$\log \chi = -(141.18/T) - 3.77814$$

for CO_2 [149].

The solubilities of hydrocarbons in liquid oxygen and the phase behavior of hydrocarbon-oxygen systems have substantial theoretical and practical interest. Predicting solubilities of chemicals in liquid oxygen is difficult because of the non-ideal thermodynamic behavior of the liquid phase. The solubilities of hydrocarbons in liquid oxygen can also be predicted by computational methods based on statistical thermodynamics [150] or EOS, cell theory partition functions and fugacities [151, 141].

3.11.2.2 Solubility of Nitrous Oxide in LOX

The solubility of nitrous oxide in liquid oxygen at temperatures between 78 and 90 K has been determined by filtering of a sample of the saturated solution, evaporating it and analyzing it by pumping away the oxygen and trapping the nitrous oxide in liquid nitrogen [152]. The solubility can be satisfactorily expressed by the equation

$$\log \chi = 0.9954 - 435.8/T$$

where χ is the mol fraction of nitrous oxide in the saturated solution. The solubility is lower than would be expected for an ideal mixture and varies over the temperature range between 2.5×10^{-5} and 14.2×10^{-5} mol N_2O /mol O_2 . The liquefied “permanent” gases are not solvents in the usually accepted sense. In fact, the only substances which will dissolve in them to any extent are other gases of comparable volatility. Ambient air contains 0.3 ppm by volume nitrous oxide which might end up in liquid nitrogen or liquid oxygen from an air liquefaction and separation plant. Nitrous oxide and carbon dioxide are unwanted contaminants in LOX, precipitating and potentially clogging filters and orifices. The solubility of N_2O in LOX must be accurately known to prevent such problems. Solubility data (χ_{N_2O} = mol fraction in liquid phase) versus absolute temperature are plotted in Figure 24 together with literature data [153]. The solubility increases sharply once the temperature exceeds the normal boiling point of LOX. Similar measurements were made for the co-solubility of nitrous oxide and carbon dioxide in LOX. Other sources [140] give the solubility of N_2O in LOX at 90 K as 140×10^{-6} mol/mol.

Accumulations of carbon dioxide and nitrous oxide in liquid oxygen may cause fouling and blockage in heat exchangers and pipelines and it may eventually cause serious explosions, like the one that occurred in Bintulu, Malaysia, in 1997. The CO_2/N_2O co-solubility has been measured in liquid oxygen at 90 K [154].

3.12 Thermodynamic Properties of Oxygen

With oxygen being a vital chemical and being known for a long time, there exists a plethora of thermodynamic data on oxygen in all physical states, including liquid oxygen which is of most interest as a rocket propellant. Unfortunately, the data do not always agree with each other, differences most likely caused by using different techniques to calibrate the equipment and the thermometers. Thermodynamic data on oxygen have been updated periodically as more accurate methods of measurement, supported by computational chemistry and modeling of the molecule, became available. The primary sources of thermodynamic data on oxygen are the JANAF tables [24] and the NIST Chemistry WebBook web site [27]. In addition, several publications provide tabulated data for heat capacity, enthalpy, and entropy of oxygen in all physical states [30, 155–160]. Because our main interest is in liquid oxygen, we have not included too many thermodynamic data on gaseous oxygen which are easy to find in the literature.

Continued developments in the design of rocket engines have resulted in the need for thermophysical properties data at higher and higher operating pressures. In an earlier interim report [161] NBS extrapolated data to 690 bar. In 1977 NBS presented new PVT measurements to 800 bar and derived thermodynamic properties from them [162]. Approximately 348 PVT data points were measured at 38 densities ranging from 15 to 41 mol/L (0.48–1.3 g/cm³) in the temperature range 58–300 K at pressures up to 800 bar. The reports include tables of the derived thermodynamic properties on iso-

bars up to 1000 bar, including density, internal energy, enthalpy, entropy, specific heats at constant volume and constant pressure, velocity of sound, and the property surface derivatives $(\partial P/\partial T)_\rho$ and $(\partial P/\partial \rho)_T$.

A review of the current status of mathematical models and correlations for the calculation of thermodynamic properties of cryogenic fluids included the thermodynamic properties of oxygen, nitrogen, and air [163]. There are now computer programs for thermodynamic properties of the fluids accessible on the Internet.

3.12.1 Heat Capacity of Oxygen

Giauque and Johnston in 1929 measured the specific heat of solid oxygen and discovered the existence of three phases, α , β , and γ . Transition temperature and latent heat are listed in Table 30. Table 31 gives a historical collection of the heat capacity of solid and liquid oxygen. Although these 1929 data that were already used in [164] are quite old, they were converted to S.I. units and kept only for comparison to more recent (and probably more accurate) data.

Table 30: Transition temperatures and latent heat of oxygen.

Data source: [26]

The heat capacity of LOX along the saturation line as a function of temperature goes through a minimum near the freezing point, probably due to beginning association of O_2 molecules (Figure 25).

Figure 25: Heat capacity of liquid oxygen (reproduced and modified from [34])

An analytical description of the heat capacity of liquid oxygen as a function of temperature along the saturation boundary $C_v = f(T)$ is required for many engineering computations. Using a reduced temperature formulation,

$$\chi = (T_c - T)/(T_c - T_t)$$

where T_c and T_t are critical point and triple point temperatures, respectively, it can be shown that a plot of $C_v \chi^{1/2}$ versus T is a straight line, except for a small deviation as the temperature approaches the critical point, Figure 26 [165].

The isochoric molar heat capacity of liquid oxygen along the saturation line (“co-existence path in a two-phase system”) can be described by the following more complicated equation:

$$C_v = [A + B\chi + C(1 - r\chi)^n] / \chi^{1/2}$$

where C_v is the molar heat capacity in $J mol^{-1} K^{-1}$, $\chi = (T_c - T)/(T_c - T_t)$ where T_c and T_t are critical point and triplepoint temperatures, respectively, r is defined as $(T_c - T_t)/T_c$, and the exponent n is selected as $n = 12$. The constants A , B and C are:

Figure 26: Heat capacity of saturated liquid oxygen (reproduced and modified from [165])

$A = 25.60277$, $B = 27.71001$, $C = -2.48274$. Using this equation, the molar heat capacity of liquid oxygen just above the melting point is $53.313 \text{ J mol}^{-1} \text{ K}^{-1}$ and at the boiling point it is $54.142 \text{ J mol}^{-1} \text{ K}^{-1}$. Integrating this equation for a temperature change between the triple point and the normal boiling point gives an enthalpy change of 1918.98 J/mol .

In expanding the temperature regime beyond the critical point pressure (50.140 atm at 154.77 K) to pressures of 350 atm at 300 K, additional heat capacity measurements were made in a range of physical conditions that is rarely encountered during storage of liquid oxygen but may well be encountered in a rocket engine for a very short time. Experimental specific heats at constant volume for oxygen in single phase domains were reported from the triple point to 300 K at pressures to 350 atmospheres [166]. A very complicated empirical equation with seven constants was used to describe specific heat over the entire domain of PT coordinates with an experimental accuracy of 1–2%. Values for the terminal slopes of PVT isochors at the coexistence boundary, $(\partial P/\partial T)_v$, were then derived for the liquid. One wonders why the authors did not publish the results in the format of a simple polynomial equation to the fourth or fifth degree that would be a lot easier to use.

Measurements of the heat capacity of solid oxygen in the temperature range from 1.3 K to about 71 K with particular attention to the behavior at very low temperatures, and in the neighborhood of the $\alpha \rightarrow \beta$ transition at about 23.89 K, led to the assumption that near 0 K each molecule moves as a single mass point with the passage of lattice waves, and the effective Debye temperature at 0 K was extrapolated to be $104 \pm 2 \text{ K}$ [167]. As the temperature rose above 10 K, the specific heat rose more rapidly than a reasonable Debye model would predict, suggesting the appearance of additional

degrees of freedom, which are thought to be the superposition of a librational motion of the molecules superimposed on the longitudinal and transverse lattice waves controlling the motion of a molecule's center of mass. The specific heat showed a very sharp high “spike” at the $\alpha \rightarrow \beta$ transition, but there was no evidence for a latent heat associated with this transition. See also [168, 169].

3.12.2 Heat of Formation of Liquid Oxygen

By definition, the standard enthalpy of formation $(\Delta H)_{298}^f$ of gaseous oxygen at 298 K and 101 kPa is 0.00 kJ/mol. Once gaseous oxygen is liquefied, heat of condensation is removed and the enthalpy of formation of liquid oxygen becomes a negative number. Enthalpies of formation of liquid oxygen reported by different sources are listed in Table 32.

Table 32: Enthalpy of formation of liquid oxygen at normal boiling point.

Molecular mass: 31.9988 g/mol

It is strange that so many aerospace thermodynamic data summaries and rocket propellant books do not include LOX at its normal boiling point at 90 K = -183 °C. Kit and Evered [171, 172] on page 183 had a completely wrong number (126.9 BTU/lb = 90.5 cal/mol). The number should be negative! Siegel and Schieler (1964) [173] lists four pages of rocket propellant physical properties but neglects to include LOX. Barrere et al. (1960) [174] shows only gaseous oxygen at 298 K, where the enthalpy of formation is zero by definition and everyone should know that. NIST Chemistry WebBook [27] does not contain the enthalpy of formation of LOX.

3.12.3 Heat of Fusion of Solid Oxygen

The heat of fusion of solid oxygen is difficult to determine experimentally because of the preceding phase changes in solid oxygen. The heat of transition of some of the phase changes may even be more than the heat of fusion. The somewhat poorer agreement for solid oxygen may be due to some characteristics in its behavior in that liquid oxygen becomes viscous close to its freezing point and readily supercools to a glass interfused with crystals of the solid modification stable just below the melting point.

A few heat of fusion data of solid oxygen are summarized in Table 33, but may not be very accurate.

Table 33: Heat of fusion of solid oxygen.

6.825	1.631	50.98	Furukawa and McCoskey	1953	[175]

Table 35 is a summary of heat of evaporation of liquid oxygen at various temperatures (at the saturation pressure for each of these temperatures). The number for the heat of evaporation at the normal boiling point was interpolated. Another compilation of measured, calculated and literature data on the heat of evaporation of liquid oxygen at different temperatures is presented in Table 36. Figure 27 illustrates the decreasing heat of evaporation of liquid oxygen between the normal freezing point and normal boiling point as a function of temperature.

3.13 Molecular Properties, Structure, Dipole Moment, Molecular Orbital Calculations of Oxygen

3.13.1 Structure of the Dioxygen Molecule

The distance of two oxygen atoms in dioxygen in the ground state triplet dioxygen is $1.21 \text{ \AA}$. The bond energy is 498 kJ/mol . The dissociation energy in the formation of atomic oxygen is equal to twice the heat of formation of atomic oxygen from molecular oxygen, $249.18 \pm 0.10 \text{ kJ/g-atom}$ at 298 K .

3.13.2 Structure of Polyoxygen Molecules

There is much interest in polyoxygen molecules O_n with $n \leq 3$, allotropes of dioxygen, as they may occur in the ozone layer of the atmosphere, in frozen or high-pressure oxygen and as short-lived intermediates in the decomposition of ozone. Here we are examining the potential for any of these molecules to be stabilized and used as a rocket

propellant. One may argue that if it is not even possible to use O_3 as a rocket propellant, how much more difficult would it be to use O_8 as a rocket propellant! Nevertheless, we need to look at O_8 and its unique properties from the standpoint of a rocket propellant chemist.

In discussing polyoxygen molecules, one must differentiate between molecules with true covalent bonds or those with loose van der Waals adducts. UV and electron beam irradiation of solid O_2 revealed a series of IR features near the valence anti-symmetric vibration band of O_3 which were frequently interpreted as the formation of unusual O_n allotropes in the forms of weak complexes or covalently bound molecules. The structure, relative energies, and vibrational frequencies of various forms of O_n ($n=1-6$) in the singlet, triplet, and, in some cases, quintet states were studied using computational chemistry [177]. The results of calculations demonstrated the existence of stable highly symmetric structures O_4 ($D3h$), O_4 ($D2d$), and O_6 ($D3d$) as well as the intermolecular complexes $O_2...O_2$, $O_2...O_3$, and $O_3...O_3$ in different conformations. For the ozone dimer, a new conformer was found which is more stable than the structure known to date.

3.13.3 Structure of Trioxygen Molecules

Trioxygen, ozone, and the several potential isomeric structures this compound may assume, are discussed in detail in *Encyclopedia of Oxidizers*, chapter “Ozone”.

3.13.4 Structure of Tetraoxygen Molecules

Most of the literature on tetraoxygen deals with the dimer of dioxygen, $(O_2)_2$. The question is if another tetraoxygen O_4 exists that is bound with covalent bonds instead of a loose van der Waals association or a collision pair of two dioxygen molecules.

3.13.5 Structure of Polyoxygen Molecules

Oxygen clusters O_8 have been observed in the ϵ -phase of solid oxygen which may be a tetramer of dioxygen $(O_2)_4$. As the pressure of oxygen at room temperature was increased to and above 10 GPa, it underwent a dramatic phase transition to a different allotrope. Its volume decreased significantly, and it changed color from blue to deep red [40]. Based on its IR absorption spectrum, researchers assumed in 1999 that this phase consists of O_4 molecules in a crystal lattice. Later it was shown by XRD that this stable phase known as ϵ oxygen or red oxygen is in fact octaoxygen, O_8 (Figure 28). No one had predicted the structure theoretically: a rhomboid O_8 cluster consisting of four O_2 molecules.

At very high pressures, solid oxygen changes from an insulating to a metallic state; at very low temperatures, it even transforms to a superconducting state. Six distinct crystallographic phases are unambiguously established. Of these, the ϵ phase of solid oxygen is particularly intriguing: it exhibited a dark red color, very strong IR absorp-

Figure 28: Molecular structure of octaoxygen.

tion, and magnetic properties. It was also stable over a very large pressure domain and has been the subject of numerous XRD, spectroscopic, and theoretical studies. But although ϵ -oxygen has been shown to have a monoclinic $C2/m$ symmetry and its IR absorption behavior attributed to the association of oxygen molecules into larger units, its exact structure remained unknown. ϵ -oxygen was then characterized by the association of four O_2 molecules into a rhombohedral box-shaped molecular unit, held together by what are probably weak chemical bonds. This structure was consistent with existing spectroscopic data and was further validated by the observation of a predicted Raman stretching mode [178, 179]. The cube-shaped molecular unit O_8 , or $(O_2)_4$, exhibits strong bonds in the diatomic units but much weaker $\pi^*-\pi^*$ bonds between them [180]. It was shown that the intracluster O_2 interaction is consistent with a donation-acceptor bond rather than the spin-pairing of two open-shell molecules [181]. Structural changes eventually lead to a structural transition at 96 GPa, as observed experimentally.

Multiconfigurational *ab initio* calculations were used to obtain a characterization of the ground singlet state of $(O_2)_4$, which is compatible with the non-magnetic character of the ϵ phase [182]. It was shown that $(O_2)_4$ is a van der Waals-like cluster where exchange interactions preferentially stabilize the singlet state. Oxygen exhibits an unusual O_8 cluster in its high-pressure solid phase. In addition, the dissociation of molecular oxygen into a polymeric spiral chain O_4 structure (space group $I4_1/acd$, θ - O_4) above 1.92 TPa pressure was predicted based on computations [183]. The θ - O_4 phase was predicted to have a similar structure as the high-pressure phase III of sulfur. Stabilization of θ - O_4 turns oxygen from a superconductor into an insulator by opening a wide band gap.

At large distances, the four triplet O_2 molecules are arranged in a way consistent with an anti-ferromagnetic structure, whereas at short distances, a significant spin redistribution is driven by the exchange process and it leads to a null magnetic moment per molecule [184]. Such behavior can be related with the magnetic evolution of solid oxygen across the $\delta \rightarrow \epsilon$ phase transition. Additional calculations of $(O_2)_4$ excited

states supported the conclusion that the relative stabilization and magnetic features of the ground singlet state are due to the onset of new intermolecular bonds, and not to an exclusive modification of the electron cloud within the O_2 molecules.

3.13.6 Crystal Structure of Solid Oxygen

Solid oxygen can exist in at least three different phases, depending on temperature and pressure (see section “Phase transitions of Solid Oxygen” on melting points and phase changes). The crystal structure of α oxygen (monoclinic, $C2m$, two molecules per cell) is consistent with O_2 molecules in contact along two rows in the (001) plane, and along two rows lying a plane that is 80.5° from (001) [185]. Contact is defined as the touching of the contours at the 0.002 level of electron density of the contoured electron density maps for O_2 . Twinning, with a twinning shear of 19° in the [90] direction on the (001) plane, should be easy; both twins and stacking faults are likely to be common and produce features in the XRD patterns. The β - O_2 phase can be seen as closely related to the α phase: if the (001) planes shear into an ABCABC... sequence and the configuration in the (001) plane is hexagonalized, the β -type structure is obtained. In this structure, if the O—O bonds are tipped about 75° to the threefold axis and precess around it, there will be contacting molecules in three directions normal to the threefold axis and along the triad axis of the rhombohedral cell. Calculated densities of the α and β phases are different at the transition temperature and the transformation is of first order.

Crystal structures and phase transitions in solid oxygen at pressures up to 13 GPa at 298 K were studied by XRD [186, 187] and Raman spectroscopy [40]. The crystal structure of the α -phase of oxygen that exists at temperatures below 23.89 K is monoclinic of space group $C2/m$. The dense packing of molecules of oxygen in this structure and the nature of the transformation from the α - to the β -phase (rhombohedral, space group $R\bar{3}m$) at 23.89 °K led investigators to conclude that there is an increase in the molar volume of solid oxygen of about 0.1 cm^3 per mol (about 0.5%) accompanying the $\alpha \rightarrow \beta$ transition and it was suggested on the basis of this volume change that the transition is of first order. The unit cell of frozen γ -oxygen is cubic, its space group is $Pm\bar{3}n$, and it has a lattice dimension of $a = 6.83\text{ \AA}$. The unit cell contains eight oxygen molecules. Oxygen molecules located at the center and corner of the cube can rotate freely, and each oxygen in the face of the cube can rotate in the plane perpendicular to the face. The crystal structure of β -oxygen is rhombohedral with a space group of $R\bar{3}m$. Its corresponding hexagonal cell has the dimensions $a = 3.307$, $c = 11.250\text{ \AA}$, and contains three oxygen molecules with their axis parallel to the hexagonal axis. The crystal structure of α -oxygen is monoclinic with $a = 5.403$, $b = 3.429$, $c = 5.086\text{ \AA}$, $\beta = 132.53^\circ$, unit cell volume = $69.44\text{ \AA}^3$, calculated density 1.530 g/cm^3 . The cell contains two molecules centered at the lattice points 000 and $\frac{1}{2}\frac{1}{2}0$, which are symmetry centers. The nearest center-to-center distances between molecules is $3.20\text{ \AA}$ and the O—O bond axis was found to be perpendicular to the a - b plane. Crystal structures did

not indicate the presence of any O_4 molecules (postulated to exist in solid oxygen, based on other observations) [188].

3.14 Optical, Electrical, and Magnetic Properties of Liquid Oxygen

3.14.1 Absorption, Emission, and Fluorescence Spectra of Liquid Oxygen

Dioxygen O_2 is the second most abundant constituent in the earth's atmosphere and vital for life on earth. The dissociation, predissociation, and band system of molecular oxygen play an important role in the aurora, airglow, and nightglow in the upper atmosphere. It is the photolysis of oxygen in the upper atmosphere that forms the ozone layer and protects life on Earth from the sterilizing UV radiation from the sun. In addition to neutral O_2 , atomic oxygen and oxygen ions like O_2^+ or O_2^- and to a lesser extent O_2^{2+} populate the ionosphere. All these are important constituents of stellar atmospheres (including that of the sun) and possibly of exoplanetary atmospheres. Even at the orbital height of satellites circling around the earth, high above the upper limits of the atmosphere, the small concentration of atomic oxygen is the most destructive species and is responsible for the degradation of elastomers, plastic coatings, paints, and solar cells in satellites.

In laboratory studies with air-filled instruments below 2000 Å, spectrographs must be evacuated because of the strong absorption of light by O_2 . This range of the spectrum is therefore called the vacuum-UV.

Photoionization cross-section measurements of oxygen are an important part of atmospheric studies. Photolysis of liquid or solid oxygen is one method to prepare ozone and other polyoxygens in the laboratory. This reaction may also occur on the cold surface of outer planets and their icy moons. Liquid oxygen and liquid ozone have been photolyzed in a search for more energetic polyatomic polyoxygen species (O_4 , O_6 , O_8) that can be stabilized at low temperatures and possibly used as rocket propellants. Atomic oxygen formed by photolysis of dioxygen is a prime reactant in atmospheric pollution studies in the oxidation of hydrocarbon vapors and formation of NO_x .

The energy levels the O_2 molecule assumes as it absorbs or emits radiation are usually designated by capitalized Greek letters, such as Δ , Π or Σ . There are several hundred publications on the spectra of dioxygen and its ionization and dissociation products, and we cannot possibly reference all of those here. Most of those publications relate to processes in the upper atmosphere. There are several good summaries that are a good starting point if one wants to study spectra of oxygen [189]. Figure 2 on page 520 of that publication shows the potential energy curves for O_2 , O_2^+ , and O_2^- and illustrates the complexity of electronic, rotational, and vibrational states and the transitions between them, each of those creating a set of absorption bands in the spectrum.

3.14.1.1 Infrared Absorption Spectra of Liquid Oxygen

Although O_2 is electrically non-polar, and the O—O bond should be IR inactive, it has a permanent magnetic moment associated with the aligned spins of two unpaired electrons. Consequently, magnetic dipole (resonance) transitions are allowed between the spin multiplet components of the ground state of O_2 , i.e., components with the same value of N , but different values of J .

Absorption intensities in the 0-0 and 1-0 bands of the infrared and the 0-0 band of the red band systems of oxygen gas were measured in the range 50–150 atm at 298 K (25 °C) [190]. The integrated absorption coefficient of each band was expressed as a power series in ρO_2 , the Amagat density of oxygen. The coefficient of the linear term $A\rho O_2$ is a measure of the intrinsic (magnetic dipole) absorption of the O_2 molecule; it was much greater in the red than in the infrared system. The quadratic term, $B\rho O_2^2$, gives the induced absorption in O_2 - O_2 collision pairs; B was about ten times greater in the infrared than in the red system.

The IR spectra of industrial grade liquid oxygen and liquid nitrogen were measured in the range 3500–1200 cm^{-1} and the absorption bands were interpreted [191]. All contaminant bands except the one at 3015 cm^{-1} assigned to methane disappeared when the liquid oxygen was treated with dried silica gel. The bands at 1286, 2219, 2458, and 2560 cm^{-1} were close to known absorption bands of nitrous oxide, N_2O . The bands at 2862, 2873, 2935, and 2962 cm^{-1} most likely belonged to hydrocarbon impurities in the LOX. The last three are close to known bands for ethane C_2H_6 . The correctness of these assignments was verified by doping a sample of LOX with N_2O or C_2H_6 and re-analyzing the sample. In the industrial grade LOX no absorption was seen in the range 3150–3350 cm^{-1} where one would expect the C—H stretching band of acetylene, a frequently observed and dangerous contaminant of LOX. A LOX sample doped with a known amount of acetylene showed a peak at 3272 cm^{-1} where it was expected.

The spectrum of solid α -oxygen deposited at 15 or 20 K consists of a sharp absorption centered at 1549 cm^{-1} (half-width $\sim 4\text{ cm}^{-1}$) and a more intense, broad absorption (half-width $\sim 45\text{ cm}^{-1}$) with well-defined peaks at 1591 and 1617 cm^{-1} as shown in reference [192]. Warming through the $\alpha \rightarrow \beta$ phase transition (at 24 K) caused the broad band to become more diffuse. Recooling restored the low-temperature spectrum and showed that the $\alpha \rightarrow \beta$ transition is rapid and reversible. None of the spectra, including those of isotopic mixtures, suggested the presence of O_4 molecules.

The prominent feature of the spectrum of crystalline α -oxygen is a temperature-dependent absorption near 27 cm^{-1} , which appears to be an anti-ferromagnetic resonance mode, the first such collective excitation to be observed in a molecular solid [193].

The IR spectrum of gaseous oxygen was examined from 1480 to 1800 cm^{-1} at temperatures between 77 and 300 K at path lengths to 200 m [194]. At all temperatures a broad structureless band was observed, which was attributed to induced absorption by colliding pairs of oxygen molecules; however, near 90 K a doublet feature appeared on top of the broad absorption which exhibited a quadratic pressure dependence and

which was assigned to a bound state oxygen dimer (O_2)₂. The energy of formation of (O_2)₂, as determined from the temperature dependence of the doublet, was $\Delta E_f = -530$ cal/mol. Part of the IR absorption of oxygen is induced by intermolecular forces [195]. A summary of infrared spectroscopy in liquefied gases with 151 references is provided in [196].

The IR absorption spectra of molecular solid oxygen O_2 have been studied at pressures up to 92 GPa at room temperature to examine the structure of the ϵ phase [197]. The IR-active vibron fundamental around 1500 cm^{-1} consisted of at least 4 absorption bands and their frequencies showed a turnover at 25 GPa with increasing pressure and then monotonically increased to 87 GPa after an initial decrease. The significant increase in the frequencies of the IR-active and Raman-active vibrons suggested a strengthening of the O—O intramolecular bond with pressure.

3.14.1.2 Raman Scattering Spectra of Liquid Oxygen

The vibrational Raman effect has been observed in both liquid and gaseous oxygen. Rotational Raman spectra have been observed only in the gas.

The pure rotational and rotation-vibrational Raman spectrum of oxygen gas at 1 atmosphere pressure has been photographed under high dispersion in the first order of a 15000 lines/in., 21-foot concave grating [198]. The molecular constants were in good agreement with those obtained from the study of the electronic spectrum.

The Raman spectrum of gaseous oxygen at 3 atm was recorded with sufficient resolution and Rayleigh-line rejection to observe the fine structure caused by the multiplicity of the rotational levels of the $^3\Sigma_g^-$ ground state of oxygen [199]. Figure 29 shows the Raman spectrum of oxygen obtained at an absolute pressure of 3 atm. It was shown that all features of the observed spectrum came from expected transitions between well-known energy levels.

Figure 29: The rotational Raman spectrum of gaseous oxygen at 3 atm (reprinted and modified from [199], with permission from © 1969 Elsevier; permission conveyed through RightsLink)

Using Ar^+ 4880 excitation, the rotational spectrum of gaseous oxygen has been obtained with enough signal-to-noise ratio that measurements of intensities of the spin satellites of the S (3) and S (5) lines were possible [200]. The agreement with calculated results was excellent. The fundamental vibrational band was measured with the Q branch lines resolved and with an intensity sufficient to see spin structure.

High-resolution (0.002 cm^{-1}) stimulated Raman spectroscopy has been applied to the study of both normal and satellite Q branches of the fundamental vibrational band of molecular gaseous oxygen [201]. Using a pulsed molecular free-expansion jet to adiabatically cool the oxygen sample, satellite Q branches at 1554 and 1558 cm^{-1} that arise due to the splitting of the $^3\Sigma_g$ ground state by spin-spin and spin-rotation interactions were completely resolved for the first time.

The SS and OO branches of the fundamental vibrational band of molecular oxygen in its electronic ground state have been resolved for the first time in Raman spectroscopy [202]. The spectra have been observed at room temperature and low pressure with a stimulated Raman scattering (SRS) spectrometer using a multipass cell. From these accurate Raman data combined with microwave data, it was possible to calculate improved values of the vibrational, rotational, spin-spin, and spin-rotation interaction constants in the $\nu=1$ vibrational state. In addition, Raman Q branches of the first and second hot bands have been recorded, allowing the determination of a set of molecular parameters for the $\nu=2$ and $\nu=3$ states, useful for future coherent anti-Stokes Raman spectroscopy (CARS) diagnostics in combustion studies.

Lattice dynamical calculations for the bulk α , β , and γ phases of solid O_2 in harmonic approximation were made from the observed Raman spectra in frozen oxygen [203]. The observed Raman lines for $\alpha\text{-O}_2$ at 43 and 79 cm^{-1} , which are both known to exhibit isotope shifts, were tentatively assigned to an accidentally degenerate line and a two-phonon band, respectively. Some discrepancies between predicted and measured spectra still must be resolved.

Detailed Raman investigations on gaseous, liquid, and solid oxygen in its α , β , and γ phases led to observation of some new features in the spectra, such as a temperature-dependent splitting of the vibrational line in $\gamma\text{-O}_2$ and a vibron-phonon combination in $\alpha\text{-O}_2$ and $\beta\text{-O}_2$ [204]. The influence of temperature on the librational line width was explained in terms of the anharmonic interaction. These data gave new information about the assignment of some of the vibration modes.

See also reference [205].

3.14.1.3 Ultraviolet Absorption Spectra of Liquid Oxygen

The photodissociation continuum of oxygen extends from 1750 to 1300 Å . The peak absorption coefficient is at about 1420 Å . The UV absorption and photodissociation of oxygen is essential for maintaining the ozone layer in the upper atmosphere and for protecting life on earth from the intense UV radiation of the sun. Consequently, the UV spectra of oxygen have been thoroughly investigated and there exist several hundred publications on this topic and an equal number on the UV spectra of ozone. On

top of that, several dozen publications reported on spectra measured with isotope-labeled oxygen. Only an incomplete random sample of oxygen UV spectra publications is referenced here. UV photolysis of oxygen is of interest for the laser initiation of oxygen/hydrogen rocket engines. The atmospheric absorption due to oxygen, ozone, and moisture very much limits the amount of astronomy that can be done from the surface of the earth. Therefore, satellites equipped with telescopes and UV spectrographs had to be sent into orbit above the atmosphere to study light from other celestial bodies (stars, planets, comets) in the UV range. The various UV absorption bands of oxygen are named after spectroscopists that first observed them:

- The Rydberg series describe the energy levels associated with almost removing an electron from the ionic core.
- Schumann-Runge bands between 176 and 192.6 nm
- Herzberg bands between 240 and 260 nm

Absorption coefficients of oxygen were measured between 300 and 1300 Å using a grazing incidence vacuum spectrograph together with a line emission light source [206]. The coefficients near 1300 Å were less than $k = 10 \text{ cm}^{-1}$. The bands in the region between 1300 and 1000 Å showed strong absorption. No strong continuous absorption was found in the region between 1300 and 740 Å. The continuous absorption of oxygen below 740 Å was interpreted as composed of the ionization continua of several Rydberg series converging to the excited states of the molecular ion of oxygen. The continuum had a broad maximum with k -values of about 700 cm^{-1} between 400 and 600 Å and, in contrast to nitrogen, still showed a large absorption of $k = 530 \text{ cm}^{-1}$ at 303 Å.

Absorption cross-sections for oxygen in the region 1850–2500 Å have been measured at different pressures, revealing a variation with pressure, probably due to the formation of $(\text{O}_2)_2$ or O_4 [207]. The values obtained by extrapolation to zero pressure varied from $15 \times 10^{-24} \text{ cm}^2$ at 1900 Å to $3 \times 10^{-24} \text{ cm}^2$ at 2300 Å. The absorption, which was about one million times weaker than that of the Schumann-Runge (S-R) system is the Herzberg continuum corresponding to a forbidden transition. The absorption cross-sections for this continuum have been calculated for different values of the internuclear distance r_e ; those for $r_e = 1.50 \text{ Å}$ agreed best with the experimental results. The calculation indicated that the maximum value of the absorption is $15 \times 10^{-24} \text{ cm}^2$ at 1870 Å. The dissociation of oxygen in the upper part of the earth's atmosphere, above 80 km, is predominantly due to absorption in the S-R continuum (1850–1350 Å), which is important in relation to the formation of the ozone layer. At wavelengths near 2100 Å the Herzberg continuum absorbs more of the sun's radiation than does the ozone continuum. Most of this absorption takes place below 25 km. The f -value of the Herzberg continuum is 3.5×10^{-5} .

The ultraviolet absorption spectra of oxygen over the wavelength range from 1750 to 2900 Å have been observed in liquid and solid media at low temperature [208]. By freez-

ing slowly from the liquid phase, samples of crystalline argon and nitrogen were prepared with added amounts of oxygen ranging between 0.01 and 10%. The Schumann-Runge bands of oxygen ($B^3\Sigma_u^- \leftarrow X^3\Sigma_g^-, 1750\text{--}2000\text{ \AA}$) were observed in solid and liquid mixtures of oxygen in argon or nitrogen at concentrations less than 5%, over the temperature range 60–90 K. The bands were broad, with half-intensity width of $150\text{--}550\text{ cm}^{-1}$ and showed no structure. At concentrations of oxygen above 5% the Herzberg bands of oxygen ($A^3\Sigma_u^- \leftarrow X^3\Sigma_g^-, 2400\text{--}3000\text{ \AA}$) were observed in the region $2400\text{--}3000\text{ \AA}$. These bands were also broad ($200\text{--}600\text{ cm}^{-1}$) and showed some partially resolved structures. No differences were observed for changes either in temperature or matrix material.

Photodissociation processes in molecular oxygen occurring in the wavelength range $500\text{--}900\text{ \AA}$ ($14\text{--}25\text{ eV}$) were investigated through observation of the resulting atomic fluorescence radiation [209]. The dispersed radiation from a continuous light source was used to excite the gas, and the resulting fluorescence radiation was observed in the ultraviolet and infrared regions. For incident wavelengths between $750\text{ and }850\text{ \AA}$ ($14.6\text{--}16.5\text{ eV}$) the electronic state from which the $1302\text{--}1306\text{ \AA}$ resonance lines are produced, was populated by predissociation. At higher energies, between $650\text{ and }770\text{ \AA}$ ($16.1\text{--}19.1\text{ eV}$), a photodissociation process occurred which produced the $1302\text{--}1306\text{ \AA}$ lines.

Discrete and diffuse absorption bands in the region $80000\text{--}100000\text{ cm}^{-1}$ were only partly assigned and may belong to various Rydberg series converging to the first ionization potential [210]. The onset of the ionization continuum was observed at $1027.6\text{ \AA}$ (97314 cm^{-1}) by photoionization mass spectrometry. Relative photoionization efficiency curves were determined to produce O_2^+ , O^+ , and O^- from molecular oxygen in the wavelength region of the helium continuum. The photoionization efficiency curve for O_2^+ throughout most of the region from $1030\text{--}580\text{ \AA}$ showed a rotationless autoionization structure, which was broadened due to predissociation and/or autoionization.

The Schumann-Runge absorption bands of O_2 in the wavelength region $175\text{--}205\text{ nm}$ were measured at high resolution with a 6.65-m vacuum spectrograph and presented in the form of an atlas showing detailed rotational line assignments containing the bands, tables of wave numbers measured for rotationally assigned principal branch lines belonging to the bands and tables of measured wave numbers of lines in the region near the dissociation limit where many unassigned lines exist [211]. The resolution of the spectra is such that $1\text{--}2\text{ nm}$ is spread over the width of a printed page and three sections fill one page of the report. See also: [212–214].

3.14.1.4 Visible Range Absorption Spectra of Liquid Oxygen

In the visible absorption spectrum of liquid oxygen peaks are located at $630, 578, 534, 478, 446, 380, 362, \text{ and } 344\text{ nm}$ [215] (Figure 30). The most intense peaks are in the yellow to red spectral region ($630\text{ and }578\text{ nm}$, respectively) and are responsible for the blue color of LOX.

Figure 30: Absorption spectrum of liquid oxygen in the visible range (reprinted and modified from [215], with permission from © 2002 American Chemical Society; permission conveyed through RightsLink)

The absorption spectrum of LOX in the visible range (Figure 31) was used to select the wavelengths for a dual wavelength analysis system, one at the absorption maximum and another away from it [216]. This allows continuous on-line measurement of contaminants (see Section 4.1.2.2, Spectroscopic Methods for Analyses in Liquid Oxygen).

3.15 Microwave Absorption Spectra of Oxygen

Radio astronomy from the surface of the earth is very much limited to a few narrow windows outside the microwave absorption of oxygen, ozone, moisture and the ionosphere. Microwave emission and absorption provides the opportunity to remotely probe our own atmosphere of earth from the outside and those of other planets using microwaves in the search for livable, oxygen-bearing extraterrestrial planets [218]. Microwave-induced plasmas in flowing oxygen, a rich source of atomic oxygen and ozone, have been tested for the detoxification of environmental pollutants. Microwave absorption spectra of oxygen and oxygen-derived species have been extensively studied by atmospheric chemistry scientists and there exists a plethora of publications on this topic. Only a few randomly selected references on microwave spectra of oxygen are discussed in this section of this book. Some may be useful for analytical purposes.

Microwave attenuation and resonant eigenmode frequency determination of microwaves reflected and forming standing waves in a metal tank can be used for propellant gauging in LOX propellant tanks, also in low-g environments [219, 220].

The absorption of radiation emitted by atmospheric oxygen in earth's sky at decimeter wavelengths ($2.71 \text{ GHz} = 6 \text{ K}$) passing through a plastic tank filled with liquid oxygen with a receiving antenna at its bottom was compared to absorption of the same tank filled with liquid nitrogen [221]. The absolute absorption factor of liquid oxygen was $\tan \delta = 7.4 \times 10^{-4}$.

The theory of the fine structure of O_2 spectra was supported by high-resolution microwave spectra, which gave the rotational constant as $B_0 = 43102 \pm 5 \text{ MHz}$ for $^{16}\text{O}^{16}\text{O}$ [222]. There is evidence for the effect of higher order terms, such as centrifugal distortion on the magnetic interaction constants.

Ten microwave absorption frequencies of the oxygen molecule in the 60-kHz region have been measured with an accuracy of about 10 kHz [223]. The result was interpreted by successfully refining the existing quantum theory. Comparing the resultant value of the rotational constant B_0 with the value obtained in UV spectra, the velocity of light was calculated to be $299773 \pm 12 \text{ km/s}$.

The theory of the rotational spectrum of the oxygen molecule was revised by correcting the calculation of the effects of centrifugal distortion of the spinning molecule [224]. Precise measurements of the center frequencies of 8 of the predicted absorption lines were made and combined with measurement of 12 lines made elsewhere to obtain the values of 7 parameters appearing in the theory. See also: [225–227].

3.16 Electrical Conductivity of Liquid Oxygen

Liquid oxygen at its normal boiling point and atmospheric pressure is a dielectric and does not conduct electricity. Under very high pressures, such as those possibly encountered in the core of gaseous planets, at high atomic concentrations, the probability of electrons tunneling from one atom to another becomes very high, the negative ions degenerate into the conductivity band, and conduction is associated with transport of these quasi-free electrons. A fourfold increase in density was attained in oxygen in the course of multiple shock-wave impact. The pressure attained a value of 190 GPa and the temperature did not exceed 7000 K. With an increase in pressure from 30 to 100 GPa, the electrical conductivity sharply increased by almost six orders of magnitude and demonstrated a very weak dependence on pressure or density on a further increase in pressure. As in the case of hydrogen, the temperature dependence of electrical conductivity in the transition region is of an activation energy type. The high pressures required to convert liquid oxygen to a conductive state can be created by single shock compression, by shock reverberation or in a diamond anvil cell.

The electrical conductivity of single shock-compressed liquid oxygen has been measured in the dynamic pressure range 18–43 GPa (180–430 kbar) [228]. The data indicated that liquid oxygen partially dissociates and formed a two-component conductive fluid.

Electrical conductivities of fluid oxygen were measured between 30 and 80 GPa at a few thousand kelvin. These conditions were achieved with a reverberating shock wave technique [229]. The measured conductivities were several orders of magnitude lower than measured previously on the single shock Hugoniot because of lower temperatures achieved under shock reverberation. Extrapolation of these data suggested that the minimum metallic conductivity of a metal will be reached near 100 GPa.

3.17 Dielectric Constant of Liquid Oxygen

The dielectric coefficient can be determined from the ratio of the capacitance of a three-terminal, flat plate or concentric tube capacitor when it is filled with liquid oxygen to that when the capacitor is in vacuum at the same temperature. One of the earliest numbers thus determined for liquid oxygen was 1.491 at 91 K (−182°C) [230].

The dielectric constant of liquid oxygen at 90 K and 1 kHz was 1.46 ± 0.01 [231].

In a study that measured the dielectric constants of oxygen, ozone, and oxygen/ozone mixtures, the dielectric constant of pure liquid oxygen at its normal boiling point (90 K) was found to be $1.46 \pm 0.01\%$ [232]. The dielectric constant of saturated liquid oxygen ranged from 1.22 near the critical point to 1.57 near the triple point [233, 234]. The uncertainty in these measurements was $\pm 0.01\%$.

The dielectric constants of compressed gaseous and liquid oxygen were measured on 10 isotherms at temperatures between 100 and 300 K and on the saturated liquid boundary at temperatures between 55 and 154 K [235]. Densities ranged from 0.06 to 1.30 g/cm^3 at pressures up to 33 MPa.

Until 2005, dielectric coefficients of liquid oxygen had only been measured either along the liquid/vapor saturation curve [234] or above 100 K for compressed fluid [235]. Additional dielectric coefficients were measured below 95 K and for pressures up to 1 MPa and are illustrated in Figure 32 [64]. Other sources [236] list the dielectric constant of LOX as 1.483 at 90.2 K and 1.507 at 84.9 K.

Figure 33 is based on one of the few data sets that clearly show the distinct deviation of the dielectric constant from linearity as the temperature of the liquid oxygen approaches the freezing point.

Figure 32: Dielectric constant of liquid oxygen (reprinted and modified from [64], with permission from © 2005 Elsevier; permission conveyed through RightsLink)

Figure 33: Dielectric constant of liquid oxygen (reproduced and modified from [34])

3.18 Magnetic Properties of Liquid Oxygen

Dioxygen O_2 is one of the few paramagnetic molecules with an even number of electrons. The ground state has a permanent magnetic moment due to unpaired spins. Oxygen is one of the few molecules that possesses a paramagnetism in the gas phase. The paramagnetism property is used to continuously measure the oxygen content of gases in flow-through on-line instrumentation, which is extremely important in administering anesthesia in hospital operating rooms. The paramagnetism of liquid oxygen can also be used to push or attract floating liquid oxygen droplets in a zero-g propellant tank and collect them at the tank outlet.

Oxygen has a triplet ground state and it becomes a magnetic liquid below 90.2 K. The magnetic characteristics can be related to the blue color of oxygen. The absorption mechanism, magnetostriction and pair correlation in the liquid were investigated through magneto-optical measurements in high magnetic fields [237].

The magnetic susceptibility (χ) of liquid oxygen is described as a function of absolute temperature (T) by the equation

$$\chi = \frac{1.01}{T}$$

where χ is the magnetic susceptibility in emu/mol and T is the temperature in kelvin. At 300 K, for example, it indicates considerably large paramagnetic susceptibility of 3.33×10^{-3} emu/mol.

It is expected from the Curie law that at low temperature magnetic susceptibility would become larger, but solid oxygen indicates extremely small susceptibility. The susceptibility of pure oxygen decreased abruptly at the melting point, again decreased sharply around 33 K and was almost constant below 33 K. At the transition point from γ to β phase, the susceptibility decreased sharply to one third. In β phase, it diminished gradually with the temperature to the next transition point from β to α phase, where it decreased abruptly once again to one half. This could be due to association of O_2 to form $(O_2)_2$ (which is diamagnetic) or to anti-ferromagnetism. There must be some interaction among oxygen molecules which reduces paramagnetism in the solid state. Many investigations have been made measuring absorption spectra, magnetic measurement, X-ray, and neutron diffraction of solid oxygen. These investigations have revealed anti-ferromagnetic interaction in solid oxygen.

The magnetic susceptibility of liquid oxygen at 90 K was measured as 2.6×10^{-4} cgs-units [238] and that of the solid at 54 K was 3.1×10^{-4} cgs-units.

Magnetic susceptibilities of single-crystal γ - O_2 and preferentially oriented polycrystalline samples of β - O_2 and α - O_2 have been measured [239]. The susceptibility of paramagnetic γ - O_2 was isotropic. The susceptibility of β - O_2 exhibited very little anisotropy but had an unusual temperature dependence which was probably due to the behavior of the lattice constants, modulation of in-plane and out-of-plane exchange interactions, and short-range order. The susceptibility of anti-ferromagnetic

α -O₂ was anisotropic, and data from five differently oriented samples were analyzed in terms of principal anti-ferromagnetic susceptibilities. This provided additional information on the crystal structure of solid oxygen phases, supplementing earlier XRD data. See also [240–243].

The shape of the liquid-vapor interface in a capillary partially filled with liquid oxygen deforms under the influence of strong magnetic fields [244, 245]. There seemed to be a relationship between the deformation of the gas-liquid interface and the square of the applied magnetic field strength in a range of 0–2 Tesla. The shape of the meniscus in a capillary tube changed from an ellipsoid into a sharp-pointed form with an increase in the field strength [246].

The extension of liquid oxygen meniscus in magnetic fields has been measured in various fields up to 5 Tesla at temperatures of 65.3 and 77.1 K [247]. It was found that the deformation of the meniscus can be determined by the balance between the magnetic normal stress and capillary pressure, which act in opposite directions at the interface.

Optical absorption spectra of solid oxygen α -phase and liquid oxygen were measured in high magnetic fields over 100 Tesla [248]. Absorption that typically originates from bimolecular transitions was observed. The spectra strongly reflected the local magnetic interaction between two oxygen molecules. The shape of the absorption spectrum of α -oxygen changed dramatically with increasing magnetic field strength, even though the absorption intensity of liquid oxygen simply declined. This difference could not be explained by the local magnetic interaction alone, and it was speculated that field-induced lattice distortion plays an important role in the solid oxygen α -phase and its visible light absorption. See also reference [188].

4 Chemical Properties of Liquid Oxygen

Oxygen is the archetype of all oxidizers. It is a stronger oxidizer than air. The increased oxidative power of oxygen in comparison to air is often demonstrated by inserting a glowing wood stick ember into a glass vessel containing oxygen, causing it to inflame instantly. Oxygen is non-toxic and sustains breathing and assimilation. Oxygen is chemically stable and can be stored indefinitely.

4.1 Assay Analysis and Quality Control

In the old days the oxygen content of grab samples of gas mixtures like air was determined in an Orsat apparatus with an alkaline solution of pyrogallol, which actively absorbed oxygen as it became oxidized to hydroxylated benzotropolone, purpurogallin. Nowadays such an apparatus can only be found in a museum, but the author remembers operating one of those apparatuses in his younger years.

Modern instruments are now available which continuously measure the oxygen content of gases and provide an instant readout and, if necessary, trigger an alarm if the oxygen content in air drops down to dangerous levels. One of the unique properties of oxygen, its paramagnetism in comparison to non-paramagnetic nitrogen or noble gases, can be used as the measurement principle in modern oxygen analyzer instruments.

4.1.1 Propellant Specifications for Liquid Oxygen

Liquid oxygen for use as a rocket propellant should meet all quality control purity requirements of the propellant specifications issued by the US military services or NASA. Type I is gaseous oxygen and type II is liquid oxygen. The grades of oxygen are as follows: grade A contains 99.6% O₂, grade B, reduced standard contains 99.5% O₂ and special grade F is 99.990% pure, for fuel cell and breathing oxygen. Requirements established in MIL-P-25508H (99.5 mass-% O₂) are summarized in Table 38 and 39 [249]. The two grades are for LOX in the as-delivered state and in the condition in which it might have been loaded into the Space Shuttle.

Table 38: Specification requirements of liquid oxygen.

Characteristic	Procured/delivered	Delivered (NASA Shuttle only)
Specification:	MIL-PRF-25508H, Type II,	Grade A SE-S-0073, Table 6.3-2
Purity	99.6% by vol. (min.)	99.2% by vol. (min.)
Alkynes as acetylene	0.25 ppm by mass (max.) for type II only	1.55 ppm by mass (max.)
Total hydrocarbon content (as methane)	50 ppm by vol. (max.)	75.0 ppm by vol. (max.)
Moisture	3 ppm by vol. (max.)	26.3 ppm by vol. (max.)
Particulate	1.0 mg/L (max.) or “continuous service”	N/A

The MIL-PRF states in 4.4.1 and 4.4.2 that analytical assay “Methods shall be selected from CGA G-4.3 except for grade F” and “Methods for analyzing impurities shall be selected from those of CGA G-4.3”. CGA G-4.3 is Commodity Specification for Oxygen G-4.3 Ed: 6 09/26/07, Commodity Specification for Oxygen, 11 pp., <http://www.cganet.com/publications.php>, http://www.cganet.com/customer/publication_detail.aspx?id=G-4.3.

Although the CGA web site writes “Any CGA publication incorporated by reference in US Federal Regulations after 1 January 2013 will be made available in a **free**, ready format online”, CGA G-4.3 is not available for free.

Table 39: Specification grade limits for oxygenper MIL-PRF-25508H (Oct 2011).

Grade	A	B	F	Test method
Purity, percent by volume, min	99.6	99.5	99.990	4.4.1
Impurities, ppm by volume, max	4000	5000	100	4.4.1
Total hydrocarbons as methane	50	67.7	20	4.4.2
Water	3	26.3	3	4.4.2
Methane	Note a	Note a	16	4.4.2
Ethane	Note a	Note a	2	4.4.2
Propane and higher hydrocarbons as propane	Note a	Note a	1	4.4.2
Nitrous oxide	Note a	Note a	1	4.4.2
Halogenated hydrocarbons	Note a	Note a	1	4.4.2
Carbon monoxide and carbon dioxide	Note a	Note a	1	4.4.2
Other (N, Ar, Kr, etc.)	Note a	Note a	75	4.4.2
Odor	Note a	Note a	None	4.4.2
Particulate ^b , mg/L, max	1.0	1.0	1.0	4.4.3

Note a: No limit established for this grade.

Note b: A filter with no more than a 10 µm nominal and 40 µm absolute rating shall be installed between the manufacturer's plant system and the manifold used to fill the gas or liquid containers for delivery.

4.1.2 Common Contaminants in Liquid Oxygen

The following compounds are found as common contaminants in liquid oxygen: nitrogen (as the result of inefficient separation in air liquefaction), water, and carbon dioxide (also carried over from the starting air). All volatile contaminants can be analyzed by gas chromatography (see section "Analytical Methods for Determination of Contaminants"). Some of the more worrisome organic contaminants may accumulate in the evaporation residues in a liquid oxygen tank or Dewar flask and form potentially explosive mixtures [250].

Experimental results indicated that a maximum safe level of hydrocarbons (e.g., hexadecane) film contamination is 100 mg per square foot [251, 252].

Mixtures of LOX and organic compounds can have friction and impact sensitivity properties similar to that of much-feared nitroglycerin [253]. One of the organics particularly worrisome is acetylene, which sometimes forms unwittingly as a product of pyrolysis of lubricating oils in hot parts of an air compressor and condenses along with the oxygen. Liquid acetylene is soluble in liquid oxygen up to 4 ppm by weight.

Comparing the solubilities of various aliphatic saturated hydrocarbons in liquid oxygen, it was noted that the solubility decreases with increasing chain length, as reported in [254]. Paraffinic hydrocarbons, such as n-decane and those typically used in lubricants, dissolve in liquid oxygen at only 1 ppm. The lower alkanes (C₁–C₄) in LOX can be detected by gas chromatography (see section "Analytical Methods for Determination of Contaminants") [255]. Liquid oxygen that has been stored in large storage containers for a long time and has been topped off many times to compensate for evap-

oration losses may slowly accumulate acetylene in its contents. If the incoming LOX contains 0.5 ppm acetylene, and the average evaporation loss is 0.4%/day, the detonable concentration will not be reached before 3 years of operation. In most cases, the turnover in a tank is faster than this period of time. The problem depends not on the size of the storage facility, but rather on boil-off losses. The 3-year safety period assumes a heat-leak loss of 0.4%/day. There are two ways to extend the period of safe operation: The first method prevents acetylene build-up by purifying the LOX introduced into the storage tank during the topping up operation. Each addition should be passed through a 6.3-kg (14-lb) silica-gel bed at a flow rate of 0.73 L/s (700 gph = 11.7 gpm), thereby eliminating acetylene and ethylene from the added liquid oxygen. The second method uses small quantities of the strong oxidizer fluorine. It was suggested that less than 0.5% of fluorine added to the LOX entering the tank would preferentially react with acetylene, and form inert soluble fluorocarbons [256]. An unusual method for removal and destruction of organic contaminants would be the addition of a small percentage (0.5 mass-%) fluorine, but that may open up a Pandora's box when it comes to subsequent corrosion problems.

It is recommended to pass the incoming LOX through an absorption column packed with silica gel which absorbs organic contaminants [257].

Carbon dioxide and water ice do not dissolve in LOX. They float about as crystals which in the worst case may clog tank outlets, filters, pumps, and injector orifices. For transfer of LOX, a filter is often inserted into the transfer lines to retain particulate contaminants (see also Figure 38).

Ambient air contains 0.3 ppm by volume nitrous oxide and 400 ppm (and rising) carbon dioxide which might end up in liquid nitrogen or liquid oxygen from an air liquefaction and separation plant. Nitrous oxide and carbon dioxide are unwanted contaminants in LOX, precipitating and potentially clogging filters and orifices. The solubility of N_2O or CO_2 in LOX must be accurately known to prevent such problems. Solubility data for N_2O or CO_2 in LOX are available in the literature [153]. The solubility of N_2O (see Figure 33, 34, and 35 in *Encyclopedia of Oxidizers*, chapter "Nitrous Oxide") or CO_2 in LOX increases sharply once the temperature exceeds the normal boiling point of LOX.

Mixtures of methane with LOX cooled to the temperature of liquid nitrogen form two liquid phases with a limited mutual solubility. Ethane also forms two liquid phases with oxygen, and in this case the mutual solubility is less than with methane and oxygen. Acetylene, carbon dioxide, and nitrous oxide are solid and virtually non-volatile at liquid oxygen temperature, and their solubilities in liquid oxygen are very small. See Tables 26 through 29.

4.1.2.1 Analytical Methods for Determination of Contaminants

Foreign materials in liquid oxygen normally come from the atmosphere and from contamination introduced during LOX production. The series "Advances in Cryogenic Engineering" contains numerous references to analytical methods for the assay and

analysis of contaminants in LOX, including [258, 259]. Other methods are described in the literature, for instance a fast method for determination of carbon dioxide in LOX [260].

4.1.2.2 Spectroscopic Methods for Analyses in Liquid Oxygen

Organic contaminants in LOX can be detected and identified using IR spectroscopic methods [261] or by gas chromatographic methods [262]. In combination with adsorptive preconcentration and 10–15 min. sampling time, hydrocarbon concentrations down to 0.01 vol.-ppm in the evolved gas can be detected.

The absorption spectrum of LOX (Figure 31 shown in an earlier section of this chapter) was used to select the wavelengths for a dual-wavelength analysis system, one at the absorption maximum and another away from it [216]. The resonant beam at 631 nm from a 35 mW laser and a non-resonant beam at 639 nm from a 5 mW laser were multiplexed and focused into a fiberoptic system and aimed into a Dewar with stair-step mirrors at the bottom to create different path lengths. The magnitude of each component beam was modulated out of phase from each other at 500 kHz and the amplitudes of modulation were balanced so that they were equal after passing through the test section at maximum attenuation. When the two components oscillated at equal magnitude, the resultant multiplexed beam maintained a constant intensity. Any lack of attenuation made the resonant beam stronger than the non-resonant beam, thus causing the intensity of the multiplexed beam to oscillate an amount equal to the difference. The detected signal was fed to a dual-phase lock-in amplifier, which directly provided the magnitude of oscillation (i.e., the difference in absorption) and the amount of contaminant in the oxygen.

Optical fiber sensors have advantages over conventional sensors, such as remote sensing, multiplexing and multi-point distributed sensing immunity toward electromagnetic interference. Laser Raman spectroscopy has been known for years as a relatively simple analytical method for identification of molecules in gases, liquids, and solids. By measuring the frequency and intensity of light inelastically scattered from the sample, LOX and LN_2 can be qualitatively and quantitatively characterized. Combining the two technologies, a Raman scattering optical fiber sensor was developed for instantly detecting and monitoring the purity of LOX in the oxidizer feed line during ground testing of rocket engines [263–266]. The Raman peak intensity ratios with different excitation light sources for LN_2 and LOX with varied weight ratios (LN_2/LOX) were measured (Figure 34). The system response time of this miniaturized sensor for LN_2/LOX measurement was in the range of a few seconds. Two frequency-doubled 532 nm cw Nd:YAG lasers and a diode laser operating at 670 nm were used as the excitation source. The 532 nm laser apparatus could measure a LN_2 percentage as low as 1% N_2 in a sample mixture. The diode laser had a poor signal-to-noise ratio and background problem.

Figure 34: Raman spectrum for 60% LN₂ and 40% LOX with a 670-nm diode laser; background-subtracted spectrum (reprinted from [264] with permission granted by © 2007 The Optical Society)

4.2 Thermal Stability, Dissociation, and Radiation Stability of Oxygen

4.2.1 Dissociation of Oxygen

The dissociation energy D^0 for the ground state of O₂ is $41260 \pm 15 \text{ cm}^{-1}$. This value was determined from spectroscopic observations.

4.2.2 Photolysis and Radiolysis of Oxygen

Under the influence of energetic radiation (UV, cosmic radiation, X-rays, γ -rays) oxygen in either gaseous, liquid or solid state dissociates and may recombine to form ozone. This is the process that takes place in the upper layers of Earth's atmosphere and results in the formation of the beneficial ozone layer. Ozone has been detected in the vicinity of icy moons orbiting Jupiter and Saturn. In the presence of water, the radiolysis of oxygen may form hydrogen peroxide. Such processes are likely to occur on the surface of icy moons of the outer planets [267]. It is known that ozone formation occurs on icy moons in the course of millennia, but it is not known if oxygen storage in orbital propellant depots or future extraterrestrial bases would result in formation of detectable amounts of ozone as the result of cosmic radiation. The γ -irradiation of liquid or solid oxygen is one method of producing ozone [268, 269].

Liquid oxygen can serve as the lasing medium for pumped lasers, emitting photons with a wavelength of 1580 nm after being excited to different excited states with

a dye laser with wavelengths of 581, 634 or 764 nm [270]. The small signal gain was 0.23, 0.3 or 0.076 cm^{-1} , respectively. The small signal gain (pumped by photons of 634 nm) was significantly higher than that of common solid-state lasers and chemical lasers.

5 Materials Compatibility with Liquid Oxygen

This book is basically a chemistry book and not a book on cryogenic system design. Properties of materials listed here are primarily examined for potential chemical reactivity. Mechanical properties due to low temperatures are only dealt with in passing. There are many better sources for cryogenic system design information out there on the bookshelves and in on-line databases than this book can offer. The change in mechanical properties due to lowered temperatures is the same regardless of which cryogenic propellant or even an inert refrigerant like liquid nitrogen, liquid argon or liquid helium the material comes in contact with. We are not dealing with mechanical properties at low temperatures.

5.1 Materials for Construction of Liquid Oxygen Systems

Liquid oxygen is not as corrosive as any of the storable oxidizers used for rocket propulsion, but at the cryogenic temperatures encountered with LOX, many materials of construction become embrittled and lose their elasticity. Due to the increased fire hazard, only non-combustible materials of construction may be used for handling of liquid or gaseous oxygen.

There are many sources of information on the selection of materials (metallic and non-metallic materials) for operation at cryogenic temperatures, foremost of all the Cryogenic Material Properties Database [271]. This database is a critical evaluation of existing experimental measurements on the properties of engineering materials at cryogenic temperatures. Equations are given for the recommended property value as a function of temperature. Since the book at hand is mostly a chemistry book and not a materials science book, these sources are offered just as references recommended for further study, but the technical details cannot be provided in this book. Those mechanical considerations in the selection of cryocapable materials are essentially the same for LOX, LN_2 , LNG or LH_2 .

In the selection of materials of construction for operation in liquid oxygen, the ignition hazard is unique in comparison to the other cryogenic propellants. Special test methods were developed to measure the ignition hazard under carefully controlled and reproducible conditions. The following sections are subdivided by metallic and non-metallic materials, preceded by a section discussing test operations where both types of materials were tested. Here is a random selection of sources of information on compatibility of materials of construction for use in LOX systems.

The literature on high pressure oxygen compatibility has been surveyed and compatibility data, such as mechanical impact sensitivity, pneumatic impact sensitivity, ignition temperature and flash and fire point for pressures above 200 bar (2×10^7 Pa) were compiled [272, 273].

5.2 Impact Sensitivity of Materials for Construction of Liquid Oxygen Systems

This section deals with impact sensitivity of all types of materials for construction of LOX systems, both metallic and non-metallic materials were tested using the same apparatus.

Many materials will ignite or explode when in contact with gaseous oxygen (GOX) or liquid oxygen (LOX) if subjected to stimuli such as a mechanical impact, shearing surfaces, adiabatic compression (pneumatic impact), or an electrical discharge in the form of a spark. Such materials must therefore be characterized as to compatibility with LOX or GOX to define the degree of hazard with their use. Generally, materials are more sensitive in GOX than in LOX and impact sensitivity is known to increase with increasing pressure. Thus, the evaluation of the sensitivity of materials in GOX is required to supplement LOX impact test data. A test program was initiated to evaluate materials being used or considered for use in oxygen systems at NASA Kennedy Space Center (KSC) [274]. The ambient pressure LOX testing phase of this program was performed at KSC, the pressurized LOX testing at Marshall Space Flight Center (MSFC), the GOX mechanical impact testing at MSFC and White Sands Test Facility (WSTF), and the flash and fire point and pneumatic impact testing at WSTF. Twelve materials were evaluated for reactivity in liquid oxygen, pressurized LOX, and high-pressure GOX. These included an aluminum alloy (6061-T6), a polytetrafluoroethylene, four filled polytetrafluoroethylenes, a polyimide, a polychlorotrifluoroethylene, two fluoroelastomers, a perfluoro ether base grease (Perfluoroalkyl Ether Lubricant Krytox[®] 240AC), and a nylon polymer. The nylon 6/6 was the only material which reacted under the ambient pressure LOX mechanical impact test conditions. Viton PLV 5010B was found to be reactive in both thicknesses with threshold pressures of 6.8 MPa (1000 psia) and 3.4 MPa (500 psia) under the conditions of the high-pressure LOX mechanical impact tests. Reactions were observed with Viton PLV 5010B and Vespel SP-21 at 6.8 MPa (1000 psia) and 3.4 MPa (500 psia) in the high-pressure GOX mechanical impact tests. The WSTF tests indicated a higher reactivity for the filled polytetrafluoroethylenes than for the unfilled resin. A statistical study of the reproducibility of the test results indicated that the major source of variability is due to the go/no go nature of the test method and that variations due to sampling and testing operations were not significant [275].

Impact sensitivity tests described in [276], mechanical impact for materials in ambient pressure LOX (Test 13A) and mechanical impact for materials in variable pressure GOX and LOX (Test 13B), pages 42–44 are patterned after the American Society for Testing and Materials (ASTM) method D 2512-82, Compatibility of Materials with Liquid Oxygen (Impact Sensitivity Threshold and Pass-Fail Techniques).

In addition to impact tests in accordance with ASTM D 2512-95 where a test specimen immersed in LOX is impacted by a hammer, an ignition test also called calorimetric bomb test according to French standard NF 29-763 is often performed. In this test, the temperature of ignition of a material heated slowly to 823 K (550 °C) under a pressure of 120 bar, is determined. Results obtained with both standardized test methods on polymeric materials, e.g. polychlorinated tetrafluoroethylene (PCTFE), polyimide, polyamide-imide, armalon, and metallic materials (nickel alloys) obtained at the University of Liège in Belgium cryogenic test facilities were presented in comparison to results obtained with a new adiabatic compression test [277]. Because rocket engines are being designed to operate at higher and higher pressures, accidental ignition by adiabatic compression is becoming an increasing concern. For this test a piece of material is submitted almost instantaneously to a high oxygen pressure which can be as high as 100 MPa while the temperature of the medium can reach ~2300 K (~2000 °C). Adiabatic compression test results were compared to ignition tests with conventional test methods [278].

5.3 Metals for Construction of Liquid Oxygen Systems

Many materials are compatible with LOX under static conditions; however, when they are used in rocket systems where dynamic shear or shock producing conditions are ever present, a severe hazard of ignition or explosion exists, and the choice of materials becomes quite limited.

Iron and most iron alloys (with the exception of the austenitic 18-8 series of Ni-Cr stainless steels) will readily become brittle at 90 K (–183 °C) and are not suitable for LOX systems. Besides the stainless steels of the 300 series the following metals can also be used and are listed here in order of increasing embrittlement at cryogenic temperatures: pure soft nickel, Monel, Inconel, copper, aluminum, annealed brass. Titanium and titanium alloys which are preferred tankage materials for many other rocket propellants can be used for LOX only with additional precautions due to their tendency to ignite in oxygen when scraped, sheared or punctured [279, 280].

The selection of metals for oxygen service is described in ASTM F.94.92 “Standard Guide for Evaluating Metals for Oxygen Service”, “ASTM G94” “Guide for evaluating metals for oxygen service”, and the test used for ranking candidate metals is ASTM G.124-95 “Standard Test Method for Determining the Combustion Behavior of Metallic Materials in Oxygen-Enriched Atmospheres”. The accidental ignition in valves and pipeline networks is often caused by particle contamination and cannot be reproduced in clean systems. A particle impact test will be able to differentiate candidate metals under more realistic conditions than clean metals only found in a laboratory, but not in real life.

A comparison of different rankings concluded that stainless steel and aluminum bronze with 9–11% Al are equivalent choices for certain oxygen valves [281].

5.3.1 Impact Sensitivity of Metals for Construction of Liquid Oxygen Systems

Since the first observation of a violent LOX/Ti reaction in early 1959, the compatibility of titanium and its alloys with LOX has received considerable attention. Initially, laboratory investigations were primarily limited to impact studies utilizing the Army Ballistic Missile Agency (ABMA) impact tester or modifications thereof. Later the US Air Force initiated programs to determine the mechanism of the reaction.

Projectile impact tests with tanks made from various materials of construction and filled with LOX have shown that impact of projectiles with only 14–28 m kp = 137–275 N m of kinetic energy can initiate even more destructive titanium metal combustion reactions. Hypervelocity impact tests with N_2O_4 in titanium, aluminum, steel, or fiberglass-reinforced plastic tanks did not result in explosions, whereas titanium tanks filled with LOX combusted with a fireball [282].

Of all the metals studied, titanium exhibited the greatest sensitivity to impact when immersed in LOX [283–292]. This friction sensitivity is like that of one of the worst materials when it comes to friction sensitivity in oxygen (or even in air): zirconium. Titanium sensitivity in contact with LOX approached that of many organic materials such as greases and oils. Reactivity was observed in liquid oxygen and mixtures of liquid oxygen and liquid nitrogen at 26.7 N m (20 ft lb) until the LOX concentration was reduced to below 30%. Titanium can be partially protected from reactivity in LOX under impact by certain protective coatings, provided the coatings are not broken. Some protection is given by electroless copper and nickel, and to a lesser extent by Teflon and a fluoride-phosphate coating. Protection is also obtained by nitriding, which adds a protective film to the surface, and by annealing which increases the thickness of the oxide film. Titanium exhibited no great reactivity in LOX when deformed by compression, by exposure of a fresh surface by machining or rupture, or by exposure of bulk titanium to high-pressure or high-velocity LOX. In gaseous oxygen, titanium was highly reactive when a freshly formed surface was exposed at even moderate pressure.

Reaction Motors, Inc. reported what they called threshold values for titanium in LOX. The threshold value is the highest impact level at which no reactions occurred out of 20 tries. Data are as summarized in Table 40.

These data indicated that the harder (aged) Ti-13V-11Cr-3Al is more sensitive than its softer counterpart, and more reactive than Ti-6Al-4V and Ti-75A.

Table 40: LOX/metal impact sensitivity.

Material	LOX impact sensitivity threshold, ft lb/in. ²
Unalloyed titanium	78
Ti-6Al-4V	78
Ti-25Zr	78
Ti-13V-11Cr-Al (solution treated)	122
Ti-13V-11Cr-3Al (aged 72 h at 627–755 K (670–900 °F))	67

Data source: as listed in [280]

Aluminum tanks filled with LOX can be ignited only by more energetic impacts, such as those encountered during the impact of meteorites in outer space. Magnesium is somewhat more easily ignited than aluminum. The reactivity of titanium in LOX can be reduced slightly by applying protective coatings. Addition of LN_2 to LOX reduces the shock and friction sensitivity of metals in LOX only after relatively large percentages of LN_2 have been added [293, 294]. Twelve materials known to be impact sensitive in 100% LOX at 10 kg m were tested in LOX/ LN_2 mixtures with incrementally increased LN_2 content until 20 consecutive tests no longer resulted in an ignition. With most materials, relatively large LN_2 additions (20–50% LN_2) were needed to reduce reaction frequencies or increase the threshold energy levels. Even highly sensitive materials did not react in 20 LOX/80 LN_2 (= liquid air), but only a slight increase in oxygen content made them reactive.

In 1959, Aerojet-General designed a test to simulate actual conditions of LOX flow through a stainless-steel loop containing a 2.5-foot section of 3/16-inch-wall, 2.5-inch ID titanium-75A tubing [295, 296]. The intent was to impact the titanium section by a drop-weight method. Before the system was completely instrumented and while the system was unattended, a reaction took place that destroyed part of the system, some burning of both titanium and stainless steel occurring. The cause of this reaction could not be established, because of the many variables; however, LOX was flowing at the time, and the pressure of the system was approximately 4.8 MPa (700 psi).

When designing an apparatus for impact testing of materials in an oxygen atmosphere at pressures from 82.7 MPa (12000 psi) to 172 MPa (25000 psi), one had to make sure that the ignition of a sample under test would not propagate to the adjacent apparatus that is confining the test atmosphere and is meant to be used more than once [297]. An existing impact tester system was evaluated for potentially extending the test conditions from 69 MPa (10000 psi) to 82.7 MPa (12000 psi) and beyond. Although the structural integrity of the impact test cell and the compressor were sufficient for operation at 82.7 MPa (12000 psi), studies revealed possible material incompatibility at that pressure and above. It was recommended that if a component should be replaced for 82.7 MPa (12000 psi) operation, the replacement should meet the final objectives of testing at 172 MPa (25000 psi). Recommended changes in the system included: use of Monel 400 for pressures above 82.7 MPa (12000 psi), use of bellows to replace the seal in the impact tester and use of a sapphire window attached to a fiber optic for event sensing.

Al-Li alloys 8090-T3, 2090-T81, and Al alloy 2219 (tempers T851, T37) were tested for compatibility with liquid oxygen using pressurized mechanical impact apparatuses at two NASA laboratories [298–300]. In addition, WSTF conducted open-cup mechanical impact and promoted combustion tests on all alloys. Reactions occurred in some specimens of all alloys during pressurized mechanical impact tests at MSFC, but there were no reactions during similar tests at WSTF.

A wide range of composition and temper variants of Al/Li alloys were fabricated and subjected to an enhanced LOX impact test [301]. In addition, each of the five alloys

were evaluated using a promoted combustion test to determine the threshold pressure and a close correlation was found between mechanical properties and LOX impact reaction frequency as defined by visual observation. Scanning electron microscopy was used to examine tested specimens. In the promoted combustion test, Al/Li alloys displayed a tenfold increase in threshold pressure compared with conventional aluminum alloys.

The series “Advances in Cryogenic Engineering” contains numerous papers dealing with the selection of materials of construction for the design of cryogenic servicing systems. This includes papers on aluminum alloys [302–304].

The German Federal Institute for Material Research and Testing (Bundesanstalt für Materialforschung und -prüfung – BAM) has developed an apparatus for testing the impact reactivity of materials in liquid oxygen under carefully controlled conditions [305] (Figure 35).

The mass of the impact weight can be varied but is normally 76.5 kg. The drop height can be varied but is normally less than or equal to 1 m. Under these conditions, the maximum impact energy is 750 N m.

Figure 35: BAM apparatus for determination of reactivity (drop weight impact sensitivity) of materials immersed in liquid oxygen (photo courtesy of BAM; reproduced with permission from BAM)

5.3.2 Friction Sensitivity of Materials in Liquid Oxygen

Metal-to-metal friction in rotating machinery may expose fresh surfaces to oxygen that may ignite. Frictional heating in oxygen equipment has been a frequent cause of oxygen accidents.

Friction and wear studies were conducted with four material combinations run submerged in liquid oxygen to determine their potential as dynamic seal components for fluorine turbopump applications [306].

5.4 Non-metallic Materials for Construction of Liquid Oxygen Systems

While the selection of metallic materials in the construction of liquid oxygen systems requires a thorough understanding of the potential hazards involved, this is even more important when selecting non-metallic (organic polymer) materials for use with liquid oxygen. Most non-metallic materials are organic materials based on hydrocarbon skeletons and as such are readily combustible in oxygen [307, 308]. In an effort to develop non-combustible non-metallic materials for oxygen service, as many C—H bonds in those conventional polymers as possible have been replaced by C—F bonds to render the material less combustible but maintain the elastic properties.

The cryogenic properties of polymer materials have received much attention with new developments and more extreme requirements in space, superconducting, electronic, and defense technologies. Polymer materials developed for these applications are mainly employed as electrical insulators, thermal insulators, sealants, and matrix materials for fiber-reinforced composites used in cryogenic environments [309]. The requirements are extremely high and complicated for polymer materials in these unique applications. The polymer materials need to possess good mechanical and physical properties at cryogenic temperatures, such as liquid helium (4.2 K), liquid hydrogen (20 K), and liquid oxygen (90 K) to meet the high requirements of the cryogenic applications. A good summary of the cryogenic mechanical and physical properties of polymer materials is given in reference [310]. This includes cryogenic shear strength, impact strength, and fracture toughness as well as cryogenic thermal, creep, sliding, and dielectric properties of polymers.

Rocket engine and rocket aircraft manufacturers observed that when some organic materials came into intimate contact with liquid oxygen, they became prone to detonation when subjected to impact or friction stimuli. When liquid oxygen was accidentally spilled on asphalt and inadvertently stepped on, the asphalt would often explode. Leather gaskets immersed in liquid oxygen and subjected to surge impact detonated with disastrous effects [311].

5.4.1 Impact Sensitivity of Organic Polymer Materials in Contact with Liquid Oxygen

The standard liquid oxygen impact test method has been modified to include a grit sensitizing agent, silicon carbide, with the test specimen [312]. The silicon carbide increased the sensitivity of the material to impact, increased the frequency of reaction, increased the intensity of the reaction, and decreased the energy required to initiate a reaction. Test data were obtained for polyethylene, Nylon 66, Kel F-81, PCTFE, and

Viton FR58/90. The surface roughness of the striker pin, the presence of silicon carbide and sample thickness were evaluated in these tests.

Foam insulation on the outside of liquid hydrogen or liquid nitrogen tanks that is not perfectly sealed and is breathing (“cryopumping”) ambient air may become soaked with liquid oxygen and constitutes an explosion hazard [313].

5.5 Lubricants for Liquid Oxygen Systems

Tribology, from the Greek word *tribos* meaning rubbing, is the science of friction, lubrication, and wear. In an oxygen environment, friction can lead to ignition, so it is important that gliding surfaces be properly lubricated; however, if the wrong lubricant is selected, that could make the situation worse rather than better. Common lubricants such as those based on hydrocarbons and intended for automotive and jet engines may not be used for LOX service, because they are somewhat soluble in LOX and can form explosive mixtures that can be initiated by shock or friction [314–316]. There are perfluorinated oligomers (oils) and polymers (gaskets) that can be used for LOX service. One of the brand names is Fluorolube®; however, some of the perfluorinated oils are reactive with magnesium or aluminum alloys and should not come into contact with these metals in the presence of oxygen. There are a few solid lubricants, such as graphite or molybdenum disulfide (brand names Molykote®, Rocol Oxylube®) that can provide lubrication of threads or slow moving shafts.

In view of the large number (more than 100) of lubricants advertised for LOX service it is difficult to identify the best lubricant for a given application and it would be best to test its performance and safety under conditions of the actual application. The situation in the early 1960s was confusing [317] and it has not improved much since.

Most hydrocarbons in contact with liquid oxygen constitute a potential explosive situation. The only organic oils, greases, waxes, and plastics which appear to be compatible with liquid oxygen are polymers which are entirely fluorinated, or which are entirely chlorinated or fluorinated with the mol ratio of fluorine being at least three times that of chlorine [318]. An investigation of the reactivity (impact sensitivity) of launch vehicle materials with liquid oxygen included samples of fluorosilicone grease [319]. A generally accepted lubricant for LOX service is Krytox® 240AC made by DuPont. See also [320, 321].

5.6 Gaskets for Liquid Oxygen Systems

Latex rubber, neoprene, butyl rubber, polyvinyl chloride or polyethylene gaskets are not suitable for LOX service because they become rock hard at low temperatures and may ignite on impact or under friction. Teflon® and Kel-F® gaskets are chemically compatible with LOX but will also lose their elastic seal qualities at low temperatures.

Unfilled Teflon gaskets will cold flow under compression and would have to be periodically retightened. The gasket industry has attempted to use glass-fiber or glass powder filled Teflon to reduce the tendency to cold flow. Some gaskets use multi-layer laminated construction of Teflon alternating with fiberglass reinforcements [322]. Other gaskets were developed specifically for use in the SATURN-V launch vehicle [323]. See also [324–328]. Some silicone rubbers and some polyurethanes maintain their elasticity down to very low temperatures, but there is concern about chemical reactivity (ignition, explosion) when impacted or subjected to friction [329].

When designing gaskets for cryogenic service, the difference in thermal contraction (or expansion) of gaskets and surrounding parts must be taken into consideration, regardless of the type of gasket and metal involved. If the coefficient of thermal expansion is mismatched, the gasket may buckle or shrink, causing leakage and/or permanent deformation. If the reader gets the impression this is a difficult task to find the right material for liquid oxygen cryogenic service, the problem is even worse when selecting materials for liquid hydrogen service where the temperatures are 50 K cooler and the temperature swings between ambient temperature and operating temperature are even wider; however, experience gained in designing cryogenic liquid oxygen systems benefits the design of liquid hydrogen systems and vice versa. Extending the cryogenic range, designers for liquid helium systems face similar problems.

In a summary of design and materials selection for cryogenic gaskets it was explained that various demountable, low-temperature static seals can be made from rectangular-sectioned gaskets of Teflon or Kel-F, or of soft metal, or with plastic sealing surfaces, but gaskets require heavy flanges for compression [330]. O-rings of rubber, Viton, and neoprene have been used successfully down to 20 K with high initial loading designs. Hollow, metallic O-rings can be used, but they are hard and require smooth surface finishes, >16 rms (root mean square). Solid O-rings of soft metals (e.g., indium, lead, copper, and aluminum) can seal to $10^{-5} \text{ atm cm}^3 \text{ s}^{-1}$ (linear in.)⁻¹ leak rates. Pressure-actuated seals of C, U, V, or W configuration are said to be superior to all others for cryogenic space systems. They use lightweight flanges and will follow flange deflections, but they are expensive, and small leak paths can develop, but they have proved reliable in the field. Temperature-activated seals (favorable thermal contraction relationships) also show promise but have not been extensively used.

Viton[®] B, a Du Pont terpolymer of vinylidene fluoride, hexafluoropropylene, and a small amount of tetrafluoroethylene, is only one of several fluoroelastomers used in some oxygen systems. The effect of formulation components and the addition of fire retardants on the impact sensitivity of Viton B fluoroelastomer in liquid oxygen was studied with the objective of developing a procedure for reliably reducing this sensitivity [331]. Component evaluation showed that almost all the standard formulation agents will sensitize the Viton stock either singly or in combination. Cure and post-cure treatments usually reduced the sensitivity of a given formulation, but no formulated Viton was as insensitive as the pure Viton B stock. Coating formulated Viton with a thin layer of pure Viton gave some indication of reduced sensitivity. See also reference [332].

Static seals are relatively easy to design when compared to rotary, dynamic seals on valve stems and pump shafts for service with cryogenic fluids [333].

Ten polymeric materials including ethylene propylene diene monomer (EPDM), Nylon 6,6, Buna-N, and other materials marketed as TFE-Teflon[®] (PTFE), Kel-F[®] 81 (PCTFE), Vespel[®] SP-21, Viton[®] A, Viton[®] A-500, Fluorel[®], and Neoprene[®] were evaluated for their oxygen compatibility [334]. The properties examined included autoignition temperature (AIT), heat of combustion, and LOX mechanical impact sensitivity. A high-pressure autoignition test rig was used for a detailed study on the materials' autoignition behavior. This high-pressure vessel is capable of measuring the AIT of a material at temperatures up to 723 K (450 °C) and at oxygen pressures (prior to a thermal excursion) up to 34.5 MPa (5000 psig). Fluorinated polymers including TFE[®], Kel-F[®] 81, Viton[®] A, Viton[®] A-500, and Fluorel[®] exhibited good oxygen compatibility. Specifically, they possessed relatively high autoignition temperatures and reasonably low heat of combustion values. Among them, TFE[®] possessed the best property by showing the highest autoignition temperature (723 K = 450 °C), lowest heat of combustion (6347 J/g = 1517 cal/g), and low LOX impact sensitivity. Vespel[®] SP-21 (15% graphite-filled polyimide) exhibited an autoignition temperature higher than fluorinated elastomers like Fluorel[®] and Viton[®] A, but lower than Kel-F[®] 81 or TFE[®]. The variation of oxygen pressure, ranging from 12.4 to 34.5 MPa (1800–5000 psig), was found to exert little influence on the autoignition temperature of the polymers. See also reference [335].

5.7 Non-metallic Tank Liners and Composite Overwraps for Liquid Oxygen Systems

Use of glass-fiber filament-wound material for applications in structures exposed to a cryogenic environment has been of interest to cryogenic engineers for quite some time. Pressure vessels for containing liquid hydrogen and for containing high-pressure gases when immersed in liquid hydrogen have been of specific interest. Most composite overwrapped tanks have a thin, flexible metallic liner to separate the contents (liquid rocket propellant, pressurant gas) from the overwrap and to reduce leakage. For expendable systems that require only a single service cycle, it has been considered to use composite overwrapped tanks with an organic polymer liner.

An early assessment of structural properties of glass-fiber filament-wound cryogenic pressure vessels pointed out the difficulties in designing and operating such vessels at low temperatures and over wide temperature swings [336, 337].

The thermal conductivity of composite overwrapped tanks and lines is less than that of metallic tanks and lines. The requirement for cryogenic propellants, such as liquid oxygen or liquid hydrogen, in current and proposed booster rockets and space vehicles, has focused attention on the determination of properties of materials at extreme subzero temperatures. The need for thermal design data at cryogenic temperatures arises mostly from two fundamental requirements: **(1)** storage and containment

of high-energy cryogenics and (2) direct exposure of space systems to the cryogenic conditions of a space environment [338].

5.8 Adhesives for Liquid Oxygen Systems

Because most organic materials become very brittle at cryogenic temperatures and lose their adhesiveness, it is very difficult to find adhesives that maintain their strength and tackiness at low temperatures. Adhesives were developed based on fluorinated polyurethanes [339–343]. Polyethers were prepared from hexafluorobenzene and hexafluoropentandiol. Polyurethanes were prepared based on perfluoropropylene oxide and tetrafluoro-*m*-phenylene diisocyanate.

In a different approach to the synthesis of oxygen-resistant fluoropolymers, copolymers of fluorinated vinyl ethers with 1,1-difluoroethene gave excellent elastomeric polymers with glass transition temperatures between 272 and 266 K (–1 and –7 °C), with a potential of forming vulcanizable polymers [344–346].

Kel-F adhesives were developed for bonding Kapton[®] foils to make positive expulsion bladders for liquid oxygen [347].

5.9 Ceramic Materials for Liquid Oxygen Systems

Despite their brittleness and lack of elasticity, ceramic materials find applications in LOX systems where combustible metals or polymers cannot be used. Some hydrostatic bearings in pumps are made from silicon carbide which withstands LOX without ignition under conditions (friction, sliding contact) where other materials would ignite [348, 349]. Tribological tests were made on a pin-on-disc apparatus using LOX as the working environment. The measurement of friction and wear allowed a comparison between different kinds of SiC ceramic matrix composites and 440C steel materials.

6 Toxicity of Liquid Oxygen

6.1 Inhalation Toxicity

Oxygen in mixtures with nitrogen is non-toxic, since these are the normal constituents of air. It is only after the oxygen content deviates from the nominal 20% that problems due to oxygen toxicity may be encountered.

Oxygen is essential to human life, but the products of its metabolism are potentially harmful to lung tissue. Manifestation of these harmful effects follows a sequence of pathological changes involving cellular proliferation, exudation, and interstitial fibrosis [350, 351]. Changes in the alveolar capillary membrane give rise to altered

metabolic pathways in the lungs which can have a subsequent effect on aspects of care directly related to physiotherapy. For example, a progressive dose-related deterioration in pulmonary antibacterial mechanisms has been demonstrated, suggesting a progressive deterioration in host resistance to inhaled bacteria with prolonged exposure to high oxygen tension. This supports the clinical impression that prolonged oxygen therapy increases susceptibility of the lungs to infection. The biochemical basis of oxygen toxicity is increased production of highly reactive, partially reduced metabolites of oxygen, including hydrogen peroxide and free radicals, by cells in hyperoxia [352]. Enzymatic intracellular defense mechanisms exist which protect cells from the toxic effects of oxygen free radicals. The physiologic manifestations of oxygen toxicity include decreases in vital capacity, diffusing capacity, and lung compliance. No effective pharmacologic means exist for lessening pulmonary oxygen toxicity in humans.

All tissues of the body can be injured by sufficiently high oxygen concentrations, but the lungs are directly exposed to the highest partial pressure of inspired oxygen. The precise concentration of oxygen that is toxic to the lungs probably depends on many variables in the exposed person, including age, nutrition, endocrine status, and previous exposure to oxygen or other oxidants. Hyperbaric oxygen accelerates the effects of oxygen toxicity and damages the central nervous system [353].

During tanking operations with oxygen at a test site or on the launch pad in the open air, the inhalation toxicity danger to personnel is usually low because the exposures are short, the cold oxygen creeps along the floor, and there is always some convection to mix oxygen with ambient air.

6.2 Frostbite Hazard

The frostbite hazard with LOX is the same as with any cryogenic fluid, for instance liquid nitrogen. It is dangerous to touch cold pipelines with a bare hand, in particular if the hand is moist because it may freeze to the cold pipe and would be difficult to remove.

Small frostbitten spots on the skin can be bathed in tepid water to alleviate the cold pain. Larger frostbitten areas or limbs may be thawed only slowly, and the patient must be immediately taken to the emergency room for treatment by a physician.

7 Handling, Transportation, Storage, Transfer, and Disposal Equipment for Liquid Oxygen

Additional information on the safe handling of LOX can be found in references [354, 355]. There are many more publications that describe the hazards of handling cryogenic oxygen and teach recommended practices for the safe handling of liquid oxygen than can be listed here. Just a few examples are shown here as a starting point

for further research: [356–360], Chap. 11 in [361], also for breathing oxygen in military aircraft [362, 363].

7.1 Storage of Liquid Oxygen

Aside from the precautions common in the handling of all cryogenic liquefied gases, the handling of liquid oxygen is relatively simple and only few additional precautions must be added to those already taken for other cryogenic liquids. Logistics must be carefully planned to take into consideration the evaporation losses during storage and transfer of LOX. The boil-off is usually simply vented to the atmosphere, but one must prevent the intrusion of ambient air, best prevented by venting through a pressure relief valve or a check valve [364]. Unlike the storage of liquid fluorine, actively cooled, zero-venting storage of LOX in a bath of liquid nitrogen is not required.

7.1.1 Storage and Transport Vessels for Liquid Oxygen

A wide range of storage and transport vessels for LOX are commercially available. All have double-wall construction to reduce heat conduction into the stored medium. The interspace between the two walls is either evacuated (like a Dewar flask) or filled with an insulating material and then evacuated. Flight-qualified rocket tanks will use a different construction since double-walled tanks would be too heavy and since usually only short hold times during countdown prior to launch are required.

7.1.1.1 Tank Cars for Liquid Oxygen Transport

Large liquid oxygen tanker cars are now in use to transport LOX from manufacturing plants to points of end use (Figure 36).

Figure 36: Liquid oxygen transport tank car. (Copyright: Linde GmbH, Pullach, Germany)

Figure 37: LOX tank cars delivering LOX through a portable filter. (Reproduced from [359] with permission from AIAA)

A typical liquid oxygen transfer operation from a transport truck to a stationary storage tank is shown in Figure 37, including the in-line filter for the removal of particulates and organic contaminants.

7.1.1.2 Stationary Tanks for Liquid Oxygen Storage

Table 41 gives an overview over evaporation loss rates for LOX tanks of various sizes with different types of insulation.

Table 41: Evaporation loss rates for LOX tanks of various sizes with different types of insulation.

Container	Net contents, kg	Type of insulation	Boil-off losses, %/day	
			Small containers	Large containers
Tanker truck	2300–8500	30–40 cm Sil-O-Gel at atmospheric pressure	10–11%	7–8%
Rail car	28000–37000	Same, but evacuated down to 0.1 mm Hg	2%	1,5%
Stationary tank farm	4500–910000	30–90 cm Sil-O-Gel at atmospheric pressure	8%	1%
Stationary tank farm	9100–53000	30–40 cm Sil-O-Gel evacuated down to 0.1 mm Hg	0.4–0.5%	0.3–0.4%

Data source: [365]

In the cryogenic industry there are LOX storage vessels in use holding up to 1500 metric tons of LOX. NASA has two LOX storage tanks at LC-39A and LC-39B with 850000 gallon capacity each at KSC that once served the SATURN-V and the Space Shuttle propellant needs and now serve the FALCON and SLS launch vehicle needs (Figure 38). In addition to the historical insulation methods shown in Table 41, there is the multi-layer superinsulation that was first used mostly for liquid hydrogen tanks but is now just as frequently used for LOX tanks. The advantages of superinsulation are lighter weight, more flexible application and lower evaporation losses; however, superinsulation is more expensive than simply evacuated double-walled tanks or powder insulation and is therefore used mostly for flight tanks. New cryogenic storage tanks use glass bubble insulation that is more effective than perlite powder.

Figure 38: Liquid oxygen ground storage tank at LC39B launch site at NASA KSC. (Photo courtesy of NASA)

LOX should be stored only in well-ventilated areas, otherwise the entire area would be exposed to increased fire hazard and more likely to burn in case of accidental ignition.

If cryogenic liquids are stored in very clean containers with smoothly polished walls, it is possible to encounter boiling delays like superheating of water in a microwave oven. Boiling delay may be encountered if the polished walls are heated suddenly or if the pressure is suddenly reduced [366]. The subsequent sudden pressure rise may rupture the tank if the vents are not properly sized. It is best to avoid boiling delays altogether by attaching porous nucleating devices (“boiling stones”) to the bottoms of the tanks or by steadily bubbling a slow stream of gaseous oxygen through the liquid.

When liquid oxygen is vented and flashed in outer space, the liquid may freeze due to the sudden loss of heat of evaporation and sublimation. The vent valves must be designed such that frozen oxygen cannot clog the vent passage [367].

7.1.2 Storage of Oxygen in the Form of Solid Oxygen

The use of solid oxygen for storage and supply systems in space applications was studied both analytically and experimentally [88]. The analysis indicated that the use of solid oxygen could provide substantially longer storage times over that obtainable with subcritical liquid and supercritical oxygen. Oxygen transport from the vacuum storage condition of solid oxygen to a condition suitable for breathing or propulsion was demonstrated experimentally by two methods, vapor transport using cryosorption pumps and solid transport by mechanically moving the solid through a pressure lock. A preliminary analysis of the transport methods indicated that the mechanical system would be the most suitable.

7.1.3 Stratification of Cryogenic Liquids

A model was developed for a stationary, non-draining, and non-forced recirculating tank containing a cryogenic fluid (LOX or LH₂) [368]. A natural convection boundary layer develops along the tank wall and transports warm fluid and less dense fluid to the top layers of the liquid in the tank. Interaction between the boundary layer flow and the previously stratified fluid depends on temperature differentials and tank geometry. The liquid and its vapor are thermodynamically coupled by allowing mass and heat transfer at the liquid-vapor interface. The model predictions matched well with experimental data in cylindrical, vertical tanks.

All cryogenic liquids tend to stratification when stored under quiescent conditions in a gravity environment in the absence of convection currents or if the upper half of the tank receives more heat than the lower half of the tank. If the upper layer is warmer (and less dense) than the lower layer, the vapor pressure in the system is above the equilibrium value [369, 370]. If a stratified tank is suddenly agitated, the vapor pressure in the ullage may collapse because colder propellant is now at the interface between the liquid and the vapor phase. The physical properties of the contents of the tank that are measured and fed to the central control computer will vary depending on the level where the sensors are installed and may give erroneous messages. For stationary installations, stratification can be avoided by attaching the support structure, which is an undesirable, but inevitable heat leakage path, at the bottom instead of the sides of a stationary tank. Convection currents in the tank will maintain the contents in a well-mixed condition. For flight tanks and rockets sitting on the launch pad during countdown, active recirculation methods will be required. The propellant can be circulated through an external loop that at the same time may contain a heat exchanger to chill the propellant, or cold helium gas can be bubbled through the tank. In a low-gravity environment, the contents of a cryogenic tank need to be stirred by jet mixing [371–373].

A numerical investigation was performed on the fluid motion inside a rocket tank with natural circulation precooling loop based on computational fluid dynamic (CFD) techniques [374]. The results showed that convection heat transfer was dominant in

the bulk above the return inlet position and the heat conduction took place chiefly below the position. The axial thermal stratification was produced in the main region of the tank, the radial stratification appeared only at the bottom and the lowest temperature region moved towards the opposite bottom header region away from the side wall near the return position.

Such a model can handle both axial thermal stratification and radial stratification which appeared in the bottom of the tank, and the lowest temperature region moved towards the right of the bottom header. A clockwise vortex was formed in the liquid phase and the velocity vortex in the bottom area of the tank changed from clockwise to anti-clockwise due to the transformation of flow field [375, 376].

The return flow location of the circulation loop plays an important part in the fluid temperature and density distribution in an oxygen tank. The 3-D distributions of temperature and velocity fields were created by computational fluid dynamics (CFD), and the effect of the return flow location on thermal stratification was analyzed [377]. It was found that a return location 2m above the bottom header is optimal, where the volume and depth of subcooled liquid oxygen in tank have maximum values.

Thermal stratification in a rocket LOX tank with a natural circulation precooling loop was numerically analyzed under different return inlet locations and influx angles [378]. It was found that the heat convection was dominant in the bulk above the return inlet location and that the heat conduction became primary below the location. The axial thermal stratification existed in the whole range of the tank, and the radial stratification appeared mainly in the bottom. The stratifications were influenced by the selection of the return inlet location and influx angle, and the optimal values of the return inlet location were at $H/L = 0.3$ and an influx angle of 30° .

The rate of self-pressurization is related to the level of pre-pressurization that existed at the moment when the tank was locked up [379]. The pressurization performance and temperature distribution in a cryogenic LOX tank was examined using a CFD model with both the vapor-liquid interface phase change and external forced convection heat exchange considered. The results showed that during the ground prelaunch holding period, intense nucleate boiling initially appears in the cryogenic tank, then the boiling intensity becomes weaker, and finally, it tends to be stable. With the high temperature gas oxygen injecting into the tank, tank pressure fluctuates among the setting pressure limits. The ullage is condensed during the whole pre-pressurization phase. Influenced by heat transferring from the ullage and the external heat leakage, the thermally stratified top layer becomes thicker with time.

7.1.4 LOX Flight Tanks

The Saturn I first stage, the S-I, was conceived in 1958 to provide early capability for large payloads in preparation for Apollo. Existing hardware was used wherever possible. The decision to arrange the engines and tanks in clusters allowed the use of

equipment developed in the Army's ballistic missile program. Thus, the uprated S-IB stage had eight 1.78-m (70-in.) diameter tanks (from the Redstone missile) surrounding a single 2.67-m (105-in.) diameter tank (from the Jupiter missile). The center tank and four of the outboard tanks were used for LOX and the other four outboard tanks were used for the RP-1 fuel. All the tanks were approximately 18.2 m (60 ft.) long, and both the LOX and the fuel tanks were interconnected at the top and at the bottom. It was important to accurately know the density of the oxidizer in order to load the correct amounts of propellants [54].

One of the most impressive LOX tanks was the LOX tank in the external tank (ET) of the NASA Space Transportation System Space Shuttle. The LOX tank was an aluminum monocoque structure composed of a fusion-welded assembly of preformed, chem-milled gores, panels, machined fittings and ring chords. It operated in a pressure range of 138–152 kPa gauge (20–22 psig). The tank contained anti-slosh and anti-vortex provisions to minimize liquid residuals and to dampen fluid motion. The tank fed into a 43-cm (17-in.) diameter feed line (Figure 39) that conveyed the LOX through the intertank, then outside the ET to the aft right hand ET/orbiter disconnect umbilical that permitted LOX to flow at approximately 1262 kg/s (2787 lb_m/s) with the Space Shuttle Main Engines (SSMEs) operating at 104% power. The LOX tank's double-wedge nose cone reduced drag and heating, contained the vehicle's ascent air data system and

Figure 39: Workers raise the liquid oxygen feedline for the 17-inch quick disconnect toward orbiter Discovery for installation. Photo: NASA

served as a lightning rod. The LOX tank volume was 550 m^3 (19563 cu. ft.) It was 8.4 m (27.6 ft.) in diameter, 15 m (49 ft.) long and weighed 5436 kg (12000 lb) empty.

Most flight vehicles do not carry insulation around their LOX tanks in order to save weight. In the early days of rocketry (A4, VIKING), a temporary, removable jacket was placed around the rocket in order to reduce evaporation losses during countdown. The jacket was then removed just prior to the launch. In most cases nowadays the LOX is topped off through an umbilical line continuously during the countdown until the tank is locked up and allowed to self-pressurize just before launch.

The frost layer that builds up during the countdown substantially reduces the rate of heat transfer and evaporation losses [380–383].

Figure 40 shows a cross-section through the LOX-air interface at the surface of an uninsulated tank wall. For simplicity, it is assumed that the temperature on either surface of the metal wall is the same, since the conductivity of the metal is much higher than that of the ice or fluids on either side. T_1 is the ambient air temperature and T_2 is the LOX temperature. The heat flux can be calculated from:

$$\frac{dQ}{dA} = k \frac{T_1 - T_2}{\Delta X}$$

The rate of heat transfer through an uninsulated aluminum tank wall from the moment it is filled with LOX gradually decreases because the frost layer has some insulating quality (Figure 41). The frost layer thickness eventually remains constant after a certain time.

Figure 40: Cross-section through the frost-coated wall of a cryogenic liquid container.

Figure 41: Time profile of heat transfer to an aluminum tank containing LOX (reproduced and modified from [380], with permission from © 1961 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

The magnitude of the heat transfer constant k is determined by components of convection, radiation, and condensation. The rate of formation of the frost layer depends on the relative humidity of ambient air. In a very dry desert climate, the frost layer may form much slower than at a launch site on the coastline where humidity is often close to saturation.

The frost layer that builds during the countdown usually flakes off during launch. Florida is a high-humidity climate and frost layers build up on cryogenic tanks very quickly. Chunks of ice breaking off from the external tank of the Space Shuttle damaged the leading edge of the wing of the Space Shuttle Columbia and caused a disaster and the loss of seven astronauts on re-entry into the atmosphere.

Aerodynamic heating during flight through the lower atmosphere increases the heat transfer into the cryogenic fluid tank. This is very pronounced in upper stages, where the heat input during maximum aerodynamic load increases by more than 3%. This is one of the reasons that many expendable launch vehicles (ATLAS-AGENA, THOR-DELTA, VANGUARD) used storable instead of cryogenic propellants in the upper stages. ATLAS-CENTAUR was the first cryogenic upper stage in the United States.

7.1.5 Storage of LOX in a Zero-g Environment

In the future, cryogenic propellants will have to be stored in orbital propellant depots where propellant is transferred to large, potentially reusable propulsion units. Experiments have been conducted to study the rate of heat transfer under zero-g conditions. Models have been developed to describe the thermal behavior of fluids in a low-gravity field [384]. One option is to store cryogenics in the supercritical state, as it was done in the LOX and LH₂ tanks for the fuel cells on the Apollo service module.

The chapter on liquid hydrogen in *Encyclopedia of Liquid Fuels*, chapter “Hydrogen”, contains a more detailed description of cryogenic propellant storage in orbital propellant depots.

7.1.5.1 Surface Tension PMDs for LOX Withdrawal in a Zero-g Environment

When transferring propellants in space, it is most efficient to transfer single phase liquid from a propellant tank to an engine. Gas bubble ingestion causes a multiplicity of problems. In earth’s gravity field or under acceleration, propellant transfer and draining a tank is simple; however, in low or zero gravity, withdrawing single phase fluid becomes a challenge.

One of the few cryogenic upper stages with multi-start capability is the Centaur upper stage and its derivative, the ATLAS V upper stage. Usually, a set of small thrusters is fired to allow the propellants in the main tanks to settle before the engine(s) is (are) restarted in orbit. As an alternative to the propellant settling maneuver, cryogenic surface tension tanks have been considered, also for orbital propellant depots [385–387].

A variety of **Propellant Management Devices** (PMD) are used to ensure single phase flow. These are routinely used for storable propellants but for cryogenic oxygen different design considerations must be applied. One type of PMD, a **Liquid Acquisition Device** (LAD) takes advantage of capillary flow and surface tension to acquire liquid. Testing with LOX at elevated pressures (and thus temperatures, maximum pressure 1724 kPa and maximum temperature 122 K) as part of NASA’s continuing cryogenic LAD development program evaluated LAD performance for LOX stored in higher pressure vessels that may be used in propellant systems using pressure-fed instead of pump-fed engines [388]. Test data showed a significant drop in LAD bubble point values at higher liquid temperatures, consistent with lower liquid surface tension at those temperatures. Test data also indicated that there are no first order effects of helium solubility in LOX on surface tension of LOX and LAD bubble point prediction. The geometry of the wire mesh pore and the fluid surface tension determine the bubble point of the screen. A high bubble point (fine screen mesh) is desirable to ensure single phase (liquid) fluid delivery and good wicking of liquid into the screen pores. Fine mesh screens, however, tend to generate a large pressure loss during outflow through the screen. The total pressure loss in the system must be less than the bubble point pressure to prevent vapor ingestion into a LAD channel.

7.1.5.2 Positive Expulsion Bladders for LOX Expulsion in a Zero-g Environment

It is very difficult to find elastomers for positive expulsion bladders that remain flexible at liquid oxygen temperatures and do not burst in flames when flexed in liquid oxygen.

Bladders made from Mylar[®] or Kapton[®] depend on adhesives that maintain their flexibility and adhesive bonding strength when exposed to low temperatures [389].

Expulsion bladders for LOX were fabricated from several different materials and evaluated by functional testing [390]. A total of 39 samples, representing several different materials in various thicknesses, were tested for LOX compatibility at 97 N m (72.3 ft-lb_f) of impact energy in accordance with MSFC-SPEC-106A. In general, only fluorocarbon and chlorofluorocarbon polymers, such as Teflon, Kel-F, Armalon, and Aclar, were acceptable. Mylar possesses excellent mechanical properties at LOX temperature. Therefore, attempts were made to desensitize this material to impact in LOX by use of insensitive metallic surface coatings, but without success. Results indicated that materials considered chemically compatible with LOX generally were not suited for fabrication of expulsion bladders because of their poor mechanical properties at low temperatures. Complex expulsion bladders involving reinforced films and predetermined fold patterns performed slightly better than simple unreinforced films.

7.1.6 Storage of Oxygen in the Supercritical State

In the supercritical state the boundary between liquid and gaseous phase disappears and the entire tank contents assume a uniform state. Oxygen required in a spacecraft for operation of fuel cells or as breathing oxygen can be stored in the supercritical instead of the liquid state. This mode of storage is used mostly for auxiliary systems in a crewed or uninhabited spacecraft and not for rocket propulsion systems but should be included here in case future small thrusters depend on a steady source of oxygen. If oxygen was stored in a spacecraft tank in the liquid state, it would be difficult to withdraw only GOX or only LOX since in a zero-g environment the phase boundary is wandering all over the tank. Surface tension propellant management systems are used mostly for storable and not for cryogenic propellants in a zero-g environment. Heat transfer to supercritical oxygen is independent of the gravity environment in which the tank is kept [391]. There are no convection currents.

The supercritical oxygen tank in the Apollo 13 Command and Service Module exploded and almost stranded the astronauts in outer space because a thermostat switch was stuck in the closed position and the tank overheated.

Oxygen is rarely stored on the ground in a supercritical state. It can be done but it does not offer any advantages over cryogenic liquid storage [392, 393].

7.1.7 Storage of Oxygen in Slush State and Densified State

If oxygen must be stored for some time before it is to be used, one might subcool it and allow some of it to freeze. During the storage time, any heat absorbed through the insulation would then go into latent heat of melting instead of latent heat of evapora-

tion and boil-off losses. Even cooling oxygen to just above the freezing point instead of actually freezing it has benefits of increased density and delayed boil-off.

Future orbital lunar and interplanetary space flights require long-term storage of cryogenics for life support, power from fuel cells and propulsion. Successful accomplishment of these missions could be enabled by optimization of high-performance insulation and other system conditions, such as initial cryogenic state (e.g., subcooled or slush) [394].

A large-scale LOX propellant densification system rated for 750 L/min. (200 gpm) and sized for the X-33 LOX propellant tank was designed, fabricated and tested at NASA Glenn Research Center (GRC) [395]. Objectives of the test program were validation of LOX production unit hardware and characterization of densifier performance at design and transient conditions. An initial series of simulated LOX densifier screening and check-out tests was done using densified liquid nitrogen instead of LOX. A second series of tests collected performance data during LOX densifier test operations with LOX as the densified product fluid. LOX X-33 tanking operations and load tests with the 75.6 m³ (20000 gallons) structural test article showed that thermal stratification occurs inside a flight-weight launch vehicle propellant tank unless a closed loop recirculation of LOX flows through the densifier and then back into the tank. Finally, in excess of 75.6 m³ (20000 gallons) of densified LOX at 66.6 K (120°R) was produced with the propellant densification unit during the demonstration program, an achievement that had never been done in the realm of large-scale cryogenic tests. Similar densification tests were planned for hydrogen to fly in the same reusable launch vehicle. While the oxygen densification unit had a capacity of 13.6 kg/s (30 lb/s) LOX, the LH2 densification unit was designed to process 3.6 kg/s (8 lb/s) of liquid hydrogen [396, 397].

The second phase of testing involved a series of closed-loop recirculation tests within a propellant test tank [398]. This testing used the densification unit in conjunction with the propellant test tank to simulate the recirculation and densification processes. For the recirculation tests the test tank was outfitted with a siphon outlet at the top of the tank and horizontal splash plates at the two fill points. A liquid level capacitance probe used to control the propellant liquid level and a series of silicon diode temperature sensors used to measure the thermal stratification were also installed in the tank. An analytical model of the in-tank densification process depended on the understanding of the effects of buoyancy-driven thermal stratification in complex-shaped tanks related to the recirculation of propellants and ambient heating. The results from the recirculation tests have confirmed the mathematical model.

7.1.8 Liquid Oxygen Property Changes During Pressurization

An analytic thermal model for pressurization and cryogenic propellant conditions during all mission phases of any liquid rocket propellant tank has been developed and validated [399]. The model assumed the propellant tanks to be divided into

five nodes and implemented an empirical correlation for liquid stratification if desired. The five nodes included a tank wall node exposed to ullage gas, an ullage gas node, a saturated propellant vapor node at the liquid-vapor interface, a liquid node, and a tank wall node exposed to liquid. Mass transfer at the liquid-vapor interface is included in the form of evaporation, bulk boiling of liquid propellant, and condensation given the appropriate conditions for each but pressurant gas dissolution was not included. Model predictions were validated by comparison with various Saturn-V era test data and reasonably successful against more recent LH2 tank self-pressurization ground test data.

The transient thermal behavior in the cryogenic oxidizer tank of a launch vehicle was theoretically investigated for the pressurization process by gaseous helium injection followed by a readiness countdown hold just prior to launch [400]. A numerical model was developed using the transient mass and energy conservation of oxygen/helium mixtures both in the ullage and in the liquid. At the liquid-gas interface, various modes of heat and mass transfer were considered, including liquid evaporation and helium absorption. Increasing the pressurization level affects tank pressure, ullage gas temperature and evaporation of liquid oxygen. As for helium absorption into the liquid, its mass is negligibly small, and it should not be a concern in design and operation of the oxidizer tank.

Ground experiments of LOX tank pressurization with high-temperature helium exceeding 600 K as the pressurant gas, and radial diffuser and anti-cone diffuser, respectively, at the tank inlet were performed and the pressurant gas requirements, axial and radial temperature distributions, and energy distributions inside the propellant tank were obtained and analyzed [401]. The tank pressure was controlled within a specified range and a stable discharging liquid flow rate was achieved. For the radial diffuser case, the injected gas impacted directly on the tank inner wall, where gas-wall heat transfer resulted in about 59% of the total input energy absorbed by the tank wall. For the pressurization case with anti-cone diffuser, the direct impact of high-temperature gas flowing towards the liquid surface resulted in a greater percentage of energy transferred to the liquid propellant, where the percentage reached up to 38%. Both of the two cases showed that the portion of energy left in the ullage in relation to the total input energy was quite small, only about 22–24%. This may indicate that a more efficient diffuser could be developed to improve the pressurization efficiency.

7.2 Transportation of LOX

Liquid oxygen is transported all over the country in a fleet of tank cars and railroad cars especially equipped for storage and transport of LOX. Several industrial gas (liquefied gas) companies have contributed to the widespread use of LOX in a variety of applications ranging from hospitals and home-bound patients with respiratory diseases to expendable and reusable space launch vehicles. These companies include

US companies such as Union Carbide (formerly Linde, USA) [402], Air Products [403] and more recently Praxair, now part of Linde US. As of 1960, Union Carbide alone had already built more than 450 trucks in more than 15 distinctly different styles with capacity ranging from 1700 to 12700 m³ (60000 cu. ft. to 450000 cu. ft). There has been a steady improvement of insulation, insulation casing, suspension, and ratio of payload to gross load.

Tank cars and railroad cars hold anywhere between 1700 and 12700 m³ of LOX. In order to minimize the sloshing of the liquid contents, which could change the center of gravity and cause vehicles to tip over, the tanks are compartmented by baffles. The valves are well insulated and located in the inside of the insulating layer, such that LOX cannot splash into passages that are extending to the warm outside world. Valve stems and pipe connections are made of metals with low thermal conductivity in order to minimize boil-off. The double-wall interspace is usually filled with porous powders and evacuated, like stationary storage tanks.

7.2.1 Logistics of Cryogenic Fluids

The logistics of cryogenic liquids, regardless of whether it deals with LOX or liquid hydrogen, require careful planning to make sure that the amount of propellant needed for a given launch application is available on the day when the launch is scheduled (and eventually postponed due to bad weather). Variables entering the equation include the boil-off of the various storage tanks, the size of the transport and supply vessels, and to a limited extent even atmospheric conditions [404]. It would be a waste of resources to store more LOX than is required to satisfy the demand [405, 406]. In the case of poor planning, as much as seven times the amount of LOX needed for a static test or a launch might be needed (wasted) for a given job.

If the distance between the LOX plant and the test or launch site is less than 10 km (7 miles), it may be more economical to install a pipeline rather than depend on a fleet of tank cars [407]. The question to be considered here is: is it necessary to transport the liquid in batches in transport containers, or can it be pumped over relatively long distances through pipelines? In the considerations of long transfer lines there are two areas which must be investigated: The feasibility of cooling down the systems and the feasibility of transferring the liquids after the line has been cooled. An accurate analysis of the cooling down transient problem is a difficult task, but one must also study the steady-state problems:

- Are equipment and techniques now available for long distance transfer of liquefied gases?
- Are the losses occurring in long distance transfers tolerable?

In the future, bases on the moon or on Mars will have to work on their own logistics using a slightly different set of parameters to keep a fleet of spaceships supplied with liquid oxygen and other propellants.

8 Flow Control Components and Instrumentation for LOX Systems

Selection criteria for components and instrumentation for LOX systems depend on the application. They are different if the application is for static testing of rocket engines on the ground, for ground service equipment at launch sites, or for the airborne (spaceborne) rocket-propelled vehicle itself. A lot of experience has been gained since the first pioneering LOX experiments of Goddard, von Braun and the likes. There is now a substantial industry of component suppliers specializing in components for cryogenic service in general and LOX in particular.

8.1 Valves

In the early days of rocketry valves were the most trouble-prone components of static test stands and flight vehicles. This has changed with the amount of experience gained as the space age matured. Now valves for LOX service are offered as off-the-shelf items and listed in on-line catalogs of component supply companies.

But even with the best valve available, improper installation can still cause problems. On the ground in stationary installations and on tank cars, problems often are caused if the valve stem and handle or actuator are covered with ice that impedes the motion of the valve stem or plunger [383]. The design of valves attempts to minimize the heat leakage into the valve (and the frosting of the exposed parts) by making the valve stems and housings from a material with poor thermal conductivity. If the valve is in an enclosure, it would help to reduce the access of ambient moisture by purging the enclosure with dry air or dry nitrogen. But even with dry air, some condensation might be observed that is due to condensing carbon dioxide. Carbon dioxide condensation is not a problem and can be easily wiped off.

A series of fires in medical oxygen tank valves in 1996/1997 caused a recall of 8000 oxygen cylinders due to incompatible valve seat materials containing polychlorotrifluoroethylene [408]. The ignitions occurred when the valve was opened for the first time after the tanks had been filled.

8.2 Quick Disconnect Couplings

Connecting a storage tank to a supply trailer or a launch vehicle requires flexible, yet leak-tight connections that can be made and unmade without a tool kit. Early models of quick disconnects for LOX are described in [409, 410]. More recent developments can be found in the catalogs of cryogenic equipment supply companies. A very large quick disconnect coupling is shown in Figure 39.

8.3 Liquid Level Indicators

The filling level of LOX tanks cannot be measured by conventional methods such as sight glasses or floats. For large stationary installations, strain gauges may be attached to the support structure to obtain a rough indication of the load in the tank. In most cases multiple sensors of the physical state of LOX vs. GOX will be arranged in an array to provide an incremental level indication.

Propellant loading of a missile or a space launch vehicle must be precisely controlled so that neither fuel nor oxidizer will be prematurely exhausted, resulting in loss of range because the remaining other component is carried as ballast. To satisfy the stringent loading accuracy requirements one must determine the true content of a tank containing LOX or liquid hydrogen.

The contents of a non-transparent tank can be measured by absorption of gamma radiation from radioisotopes. LOX would absorb more radiation than GOX; however, if the tank is covered with a crust of ice, the gamma ray absorption of ice would give false results.

Liquid level gauges based on measurement of the dielectric constant in a laddered capacitance circuit are widely used, also in cryogenic tanks that supply breathing oxygen to military aircraft [411].

One of the less accurate, but quite fundamental methods is simply measuring the hydrostatic pressure at the bottom of a vertical stationary LOX tank.

One of the more popular gauges for measuring liquid level is the differential pressure gauge frequently known as the Delta-P system. This device is adequate for many simple applications but has deficiencies where a gauge is required to provide information for a complex control system requiring extremely high accuracies and fast responses. Ultrasonic gaging is more accurate and widely applicable to cryogenic and non-cryogenic fluids [412]. The reflection of ultrasound either looking down at the liquid surface or looking up from the liquid at the bottom and measurement of the time of travel will allow one to determine the location of the phase boundary.

Another simple method is a resistance measurement of a hot wire immersed in the fluid. Its heat loss and resistance in liquid would be higher than in gas [413]. Special care must be taken not to heat the wire to the point where it might ignite in an oxygen atmosphere.

Some of these liquid level gauges are suitable only for stationary installations. Liquid level gauges for flight tanks must meet more stringent requirements. A liquid level gauge in the SATURN-V booster was based on a capacitance measurement [414]. Data from both oxidizer and fuel liquid level gauges were fed to a computer which was capable of adjusting the mixture ratio toward the end of the burn such that all propellant was consumed, and no puddles of unused propellant sloshing around would cause the vehicle to go unstable.

An optical fiber-based liquid level detection system for applications in cryogenic environment consisted of a multiplexed array of point liquid probes [415]. Two dif-

ferent designs of the probe were fabricated and tested. The multiplexing of multiple liquid probes using an optical time domain reflectometer (OTDR) device was successfully demonstrated.

Other liquid level gauges measure the difference in the thermal diffusivity in the vicinity of a hot wire [413]. The difference is mostly due to the difference in heat capacity of the two states of fluids: The heat capacity of oxygen at the normal boiling point are $1.699 \text{ J g}^{-1} \text{ K}^{-1}$ for the liquid and $0.910 \text{ J g}^{-1} \text{ K}^{-1}$ for the gas, with a gas:liquid ratio of 1:1.87, giving a more distinct reading than hydrogen, where the liquid:gas ratio of heat capacities is only 1:1.26.

Most of the instrumentation intended for density measurement of cryogenic liquids can also be used for liquid level sensing [416]. This includes dielectric constant/capacitance, resonant cavity, nuclear radiation attenuation, acoustic reflection, and forced harmonic oscillation.

Radio frequency sensors can be used for measurement of the quantity of liquid propellants in tanks of space vehicles both on earth (during their fueling) and in low gravity and zero gravity conditions during space flight [417].

Other liquid level gaging systems are described in references [418, 419], and [420].

A sensor consisting of a vertical linear array of 140 highly sensitive optical fiber refractometric transducers with a measurement range of 1.6 m with a resolution of up to 5 mm can be used for measuring the level of any cryogenic liquid such as LOX or liquid hydrogen [421].

8.4 Flow Meters

Flow meters for LOX can be either turbine flow meters or differential pressure gauges [422]. An integrating flow meter was required for dispensing LOX from tankers. A considerable number of positive displacement metering principles are in existence, but they are mainly developed for water meters. The rotary or oscillating piston meter is simple to manufacture because metering chamber and metering pistons are easily machined. A summary of information on flow meters for LOX service is given in [423].

One of the problems associated with the use of cryogenic fuels and oxidizers in rocket engine testing is that of accurately determining propellant flow rates, thereby providing essential information for the prediction of thrust and specific impulse. While many diversified approaches have been investigated for the measurement of propellant flow rates ranging from the now familiar turbine-type flow meter to the more exotic magnetic and ultrasonic-type flow meters, all of these systems have a common problem, i.e., even though a highly accurate flow meter may be developed, the limiting factor is the overall system accuracy including the error in calibrating the flow meter. High flow rate, open-loop type flow meter test stands have been widely used in calibration of flow measuring devices with non-cryogenic fluids; however, the calibration of flow meters using cryogenic fluids which are subjected to rapid boil-off

precludes the use of a system which is open to ambient conditions. In addition, cryogenic fluids inherently exhibit significant density changes as the temperature of the fluid varies. Inasmuch as most cryogenic systems are maintained under a pressure sufficient to insure subcooling of the liquid, the temperature-density variation could occur without cavitation but still present unique problems in determining the flow rate. Calibration of these flow meters can be achieved within ± 0.17 mass-% or ± 0.28 vol.-% by the method described in reference [424].

If a flow meter is calibrated at room temperature with water prior to calibrating it with LOX or LN_2 , it may be difficult to extrapolate from the water-room temperature calibration to the cryogenic fluid calibration [425, 426]

8.5 Pressure Gauges and Pressure Transducers

Pressure transducers for cryogenic service must have the capability to compensate for changes in temperature. The calibration of many pressure (load) sensing elements drifts substantially as soon as the temperature changes [427]. A summary of pressure measuring instrumentation for LOX service is given in reference [428]. All transducer types of pressure transducers, such as strain gauge, capacitance, potentiometric, or piezoelectric, were included and their uses with gaseous or liquid oxygen were reviewed.

8.6 Temperature Probes

Cryogenic temperatures are usually measured accurately with resistance thermometers. Early in the development planning for liquid hydrogen-oxygen rocket engines, it became apparent that routine high accuracy temperature measurements in the cryogenic ranges of liquid hydrogen and liquid oxygen would be necessary. Although these measurements had been accomplished in research laboratories, "ruggedized" sensors and associated equipment suitable for continued use in outdoor test stands had to be developed. A ruggedized system was developed that will, with individual calibration, provide measurement accuracy of $\pm 0.1^\circ\text{F}$ [429].

9 Transfer and Pumping of LOX

The transfer of LOX between stationary tanks, between transport tanks and stationary tanks, or from ground service tanks to flight vehicles must usually be completed with a minimum of time and a minimum of evaporation losses during transfer. Because it involves moving parts (pump shafts, valve stems), friction must be avoided since it has been the cause of several LOX transfer accidents. When filling flight tanks on

a launch pad, one describes the entire operation as “fueling a rocket”, but one hesitates to use the word “fueling” when actually the oxidizer is described. We prefer the more general, less specific term “tanking” which would cover either oxidizer or fuel without any chance of confusion.

LOX can be transferred by pressurizing a tank or with pumps. Of course, if the geographic arrangement allows this, it could also be gravity fed from a tank on a high ridge or on a high tower like a water tower. Even if pumps are used, the supply tank is often pressurized somewhat to maintain a net positive suction head and prevent cavitation in the inlet section of the pump.

Regardless of which method of transfer is used, under no circumstances may liquid oxygen be trapped in a section of tubing or hose between two closed valves if the transfer line is not jacketed with liquid nitrogen (which is rarely done). The stagnant LOX would warm up and the pressure would increase by thermal expansion of the liquid and/or increasing vapor pressure to beyond the pressure rating of the equipment. If LOX is allowed to achieve room temperature in a constant volume vessel, the pressure would increase to $247 \text{ MPa} = 2440 \text{ atm}$. Only few vessels can withstand such a pressure. Transfer systems will typically be designed such that each section carries its own sets of pressure gauges and pressure relief valves.

9.1 Pressurized Transfer

Gas-pressurization is a simple and commonly used method for feeding propellants into rocket combustion chambers. Nitrogen and helium are often used for pressurizing liquid oxygen. Ideally, the pressurizing gas should neither dissolve in the propellants nor condense in the tanks; helium is preferred on both counts. Nitrogen is considerably cheaper than helium and is widely used, especially with systems operated at earth surface ambient temperatures; however, for use at the low temperatures required with liquid oxygen, nitrogen is far less attractive than helium. At these low temperatures and at the pressures of interest, the nitrogen can dissolve in the oxygen to the extent that the propellant is seriously diluted. The dilution may vary from negligible amounts to equilibrium concentrations, depending on the elapsed time between pressurizing the tank and discharging its contents and on the rate at which equilibrium is attained. Therefore, both the equilibrium state of the oxygen-nitrogen system and the rate of solution are factors that must be considered when studying the feasibility of using nitrogen as a pressurizing gas.

When a tank containing a cryogenic liquid is pressurized with a pressurant gas, the pressurant gas slowly diffuses into the liquid from the liquid/vapor interface. In the absence of any mixing mechanism (such as convection or stirring), the diffusion of the solute molecule *A* into the solvent liquid *B* is governed by a diffusion equation. For a tank with a simple flat liquid/vapor interface, the problem can be considered one-dimensional. Imposing initial conditions of no solute in the liquid initially, and

an equilibrium concentration of solute c_0 at the interface for all times $t > 0$, the concentration of solute A in B at later times can be calculated.

Because LOX tanks are typically not designed to withstand excessively high pressures, pressurized transfer must be performed with a number of precautions to prevent inadvertent overpressurization of the supply tank. This will limit the flow rate at which propellant transfer can be achieved. For higher flow rates, pumps will be required. It makes a big difference if the pressurization of a cryogenic tank is done only to provide sufficient net positive suction head at the pump inlet to prevent cavitation, or (in the absence of pumps) the pressurant gas does the work of expelling the fluid from the tank (often against the substantial back pressure of propellants reacting in the combustion chamber).

LOX can be transferred under its own vapor pressure if the rate of heat conduction into the tank is known and if one has enough time to wait for the vapor pressure to overcome the hydrostatic pressure required to lift the liquid above the top of the tank. If one does not have the time to wait and transfer must be achieved at short notice (as in the old days when LOX-propelled ICBMs were on alert all the time and had to be fueled at a moment's notice), compressed helium or hot oxygen gas can be used to pressurize the tank. In many cases it may be more economical to use compressed nitrogen instead of compressed helium for LOX transfer, at least for ground operations. In these cases, one must take into consideration that some of the pressurization gas will dissolve in LOX and dilute it [430].

Depending on the amount of turbulence in the vapor space and at the liquid/vapor interface, the rate of nitrogen condensation may be tolerable. A small cryogenic transfer system was constructed and tested with LOX and LN_2 [431]. Transfer pressures were varied between 441 kPa and 3.2 MPa (50 and 450 psig). The test tanks were immersed in a vented tank of LN_2 so that LOX could be transferred in a sub-cooled thermodynamic state. Tests were carried out in which (1) an empty tank was pressurized, and the pressure was then held for 1 min, (2) a tank full of liquid was pressurized and liquid transferred to a receiver tank within 1 min. Gas requirements and tank temperatures and pressures were measured in each test. Estimates of the condensed gas and the residual cold gas were made from material balance calculations. In one run, LOX was pressurized and transferred with N_2 gas. Samples of LOX were taken in the receiver tank and analyzed for inert gas contamination. No contamination of the transferred LOX was noted. An analytical model was proposed for calculating the rate of heat transfer to the walls and liquid. The heat transfer estimation was combined with an equivalent mass concept derived from thermodynamics to yield estimated values of gas consumption. The calculated values of pressurization gas requirements for all runs were within $\pm 15\%$ of experimental values. Similar expulsion tests were performed with LN_2 as a substitute for LOX [432].

One of the first operational ICBMs with LOX was the ATLAS-I. The tanking ("fueling") system used compressed oxygen instead of compressed nitrogen to prevent dilution of LOX by inert pressurant gas [433]. Nitrogen dilution of LOX should be limited to

below 0.5 mass-% to minimize performance losses and changes in physical properties of the oxidizer [434, 435]. If helium is used as a pressurant gas for LOX, only very little helium dissolves in LOX [139].

In designing a main tank pressurization system, direct impingement of the gas jet on the cryogenic liquid surface is avoided. If the warm pressurant gas is slowly diffused into the head space (ullage) without turbulence, it will stratify which in this case is desirable because it will require less gas to achieve complete pressurization. The amount of pressurant gas will vary from one event to the next. The gas consumption depends on the filling status, the heat capacity of the tank wall, the heat capacity of the pressurant gas, the feed pressure, and the vapor pressure and heat of evaporation of the cryogenic liquid being pressurized. Equations have been developed that can be used to predict pressurant gas requirements [436]. See also [437–443].

If enough pressurant gas is available, it can be precooled to achieve more reproducible pressurization sequences.

9.1.1 Propellant Dilution Due to Pressurant Gas Condensation

If LOX is transferred by pressurization of the source tank with helium, it must be taken into consideration that some of the pressurization gas will dissolve in LOX and dilute it [444].

A method for determining the composition and phases existing within a propellant tank when LOX is pressurized with N_2 gas assumed that the pressurizing gas flows adiabatically from the pressurization gas tank and that an equilibrium state exists in the oxygen-nitrogen system [445]. Enthalpy-concentration plots for the oxygen-nitrogen mixtures at constant pressures from 0.698 to 4.14 MPa (100–600 psia) were provided to quantify the dilution. Both the equilibrium considerations and a small amount of experimental testing led some investigators to conclude that gaseous N_2 is unsuited for pressurizing liquid-oxygen systems. A 42-L (1.5 cu. ft.) cylindrical tank the size of a H-cylinder was filled with LOX and pressurized with nitrogen at 3.1 and 6.2 MPa (450 and 900 psia) and allowed to stand for 6 or 10 min. After withdrawing about half of the contents, the oxygen concentration dropped from 100 to 70% O_2 , indicating that significant dilution had taken place in the top layer of the tank. See also [446].

The penetration of gaseous N_2 into LOX at a pressure of 1.03 MPa (150 psia) was determined by monitoring the composition of the evaporating liquid in a nitrogen analyzer [447]. For pressurization times of about 1 h, the penetration depth varied between 0.06 and 0.45 mm (0.0024 and 0.018 in.) at an evaporation rate of about 1 gallon/day. In a quiescent tank where evaporation losses are taken from the surface, the contaminated surface partially cleans itself of condensed nitrogen.

The penetration of pressurizing gaseous nitrogen (GN_2) into LOX was investigated experimentally by measuring the extent of LN_2 build-up at the LOX interface as a function of GN_2 pressure [448]. Then an adaptation of the differential flash

evaporation technique was used to determine the binary diffusivity of the LOX-LN₂ system at a temperature of 90.2 K. The measured value D equals $0.000086 \text{ cm}^2/\text{s}$, which together with two prior measurements at lower temperatures revealed an excellent fit to the Arrhenius equation, yielding a pre-exponential factor $D_0 = 0.0452 \text{ cm}^2/\text{s}$ and an activation enthalpy H of 1.08 kcal/mol . At a pressure of 11.7 MPa (1700 psi) and holding time of 15 min , the depth of penetration of LN₂ into LOX (to a 1% contamination level) was found to be 0.9 cm .

9.2 LOX Pumps

The cryogenic equipment industry has developed LOX pumps for many applications and flow rates [449].

The selection of ignition-resistant and burn-resistant materials is a major factor in the design of 75000-rpm turbopumps, which can deliver 2.7 kg/s (6 lb/s) of liquid oxygen at 34 MPa (5000 psig). The potential operational hazards of rubbing friction and the impact of foreign particles at high velocity were investigated experimentally for a wide range of candidate materials including nickel, copper, Monel, CRES-316, Hastelloy-X, Invar-36, and silicon carbide [450]. Test parameters included oxygen pressures up to 34 MPa (5000 psig) and temperatures up to 700 K (800°F). The applicability of these materials to oxygen pump design was ranked by comparing the experimental results among themselves and an analytically determined parameter, called the burn factor. Nickel and copper demonstrated superior resistance to ignition and burn in the friction rubbing and particle impact tests relative to Monel, stainless steel, and nickel-iron base superalloys.

The best way to prevent contamination of pumped LOX by leakage from the turbine housing along the pump shaft is to operate the turbine on the same chemical as is being pumped as a liquid on the other end of the shaft: oxygen. A LOX pump turned by 477 K (860°R) hot oxygen driven turbine was designed for a 16.5-kN (3750-lbf) thrust dual expander cycle rocket engine [451]. This turbopump, which required no interpropellant seals or seal cavity purges was driven by a 116-kW (156-HP) single stage turbine. The pump was made of Monel, which has a low ignition potential in oxygen and delivered 2.18 L/s (34.7 gal/min) LOX at 32.1 MPa (4655 psia) at a shaft speed of 75000 rpm .

Various trade organizations have issued standards for design and installation of stationary LOX pumps [452].

9.3 Chillardown Losses During LOX Transfer

When transferring LOX between transport and storage tanks or between launch site storage tanks and flight vehicles, a substantial amount of LOX is lost by evaporation until all the conduits, valves, pumps, and receiving tanks are chilled to LOX temper-

ature [453]. These boil-off losses can be reduced if LOX is chilled to below the boiling point prior to the transfer operation. This requires additional energy and additional equipment and one will have to conduct a trade-off study from case to case to see if the potential LOX savings will justify the additional expense [454].

The transient behavior of a small-scale cryogenic transfer line was investigated during chilldown to cryogenic temperatures [455]. The vacuum-jacketed apparatus consisted of a vertical tube followed by a near-horizontal tube. The tube diameter was 1 cm and the overall length was 4.4 m. The apparatus was equipped with view ports in the near-horizontal section to allow visual observation of the flow patterns. Wall temperatures were measured at various locations along the length of the transfer line. Each test was conducted at a constant liquid volumetric flow rate at the transfer line inlet until saturation temperatures were obtained throughout the system. Liquid flow rate was varied by more than two orders of magnitude and resulted in chilldown times ranging from a few minutes to several hours. An optimum flow rate exists that minimizes liquid consumption during the chilldown process. At higher flow rates, there is insufficient time for heat transfer from the liquid to the wall and inefficiencies result from the greater amount of incompletely vaporized liquid passing through the system. At lower flow rates, chilldown time and total ambient heat leak into the system increase, which raises liquid consumption.

Evaporative losses during transfer can be calculated theoretically if the heat capacity and the mass of the receiving tank are known. For instance, if a 2300-L aluminum tank weighing 136 kg is to be filled with LOX, only 4% of the total mass of LOX is lost [456]. If LOX is prechilled to 80 K, one will not only avoid LOX losses during transfer, but a 2300-L tank in a launch vehicle which may have evaporation losses of up to 3%/h will not lose any oxygen for the next 80 min, while the vapor pressure in the tank comes up to atmospheric pressure. There are other reasons why one will want to prechill LOX prior to transferring it. Flow rate measurements in turbine flowmeters are inaccurate (excessively high) if the liquid is boiling and a two-phase mixture of liquids and bubbles keeps the turbine spinning. Even though the merits of cryogenic fluid metering are well known, the means of accurately doing this are not so well established. Flow measurement is useful in those applications that involve gases or liquids in processes which either produce or use cryogenic fluids. The measurement of cryogenic fluid flow is a difficult task. To a large part this is due to the very nature of the fluids being measured. Cryogenic fluids generally exist as saturated fluids. Pipe runs are generally short. Differential pressure measurement associated with head-type meters is often difficult. Because of the extremely low temperatures involved, thermal effects are significant. Pressure drop through a flowmeter must be kept low to avoid superheating the fluid. Cryogenic fluids provide little or no lubrication for meter bearings [457]. If the liquid is below its boiling point, more accurate flow rate measurements are possible. The effective density of boiling LOX is much lower than that of non-boiling LOX and this must be taken into consideration if filling a flight vehicle by volume instead of mass [458–460].

Instead of chilling LOX by recirculating it through an externally cooled heat exchanger, it can be cooled by bubbling very cold helium gas directly through the liquid [461].

Sub-cooling of cryogenic propellant by helium injection is one of the most effective methods for suppressing bulk boiling and keeping sub-cooled LOX during the countdown prior to rocket launch. Since the injected helium is pure, the difference in the partial pressure of the oxygen in the helium bubble and the vapor pressure of the LOX causes diffusional mass transfer of oxygen into the helium gas. This diffusion process (or boiling process) results in a cooling effect caused by the absorption of evaporation heat from the surrounding LOX. An analytical model for the helium injection system was developed that described the bubbling system using finite-rate heat transfer and instantaneous mass transfer concepts [462]. With this simplified approach, the effect of helium injection into LOX system under several circumstances could be studied. Experimental results along with simulations of single bubbles rising in LOX are reported with various helium injection flow rates, helium temperatures and injection methods. The injected helium does not have to be pre-cooled below the oxygen temperature. Some oxygen is lost with the helium that becomes saturated with oxygen. See also reference [463].

The full rate of transfer of LOX between tanks can be achieved only after the entire conduit has cooled to the temperature of LOX. If LOX was too rapidly splashed in conduit sections, it might cause sudden pressure spikes. The industry has developed sensors which indicate the proper cooling status of pipeline sections before throttling up to full flow rates [464].

Similar to the calculations for predicting the cooling time for a receiving vessel (discussed earlier), the cooling time required for a pipeline section can be calculated analytically [465]. The type of flow when the fluid emerging at the end of the pipeline is only a mist of droplets instead of a bubble-free liquid is called "*mist flow*". In some instances, not only one but even two or more rocket stages may have to be filled with LOX at the same time and cooldown time is critical for the mission [466].

Cooldown losses of LOX can be avoided altogether if the transfer line is jacketed with an outer shell filled with liquid nitrogen; however, such an elaborate plumbing set-up is rarely used. Instead of lining the entire length of the pipeline with LN_2 , it is sometimes more practical to pass the LOX through a heat exchanger immersed in a tank with LN_2 to cool LOX from 90 to 77 K prior to entering the long transfer line and thus reduce the boil-off during transfer.

An uninsulated 10.2-cm (4-in.) diameter pipeline may absorb $455 \text{ kcal h}^{-1} \text{ m}^{-1}$. After it is covered with a frost layer 4 mm thick, the heat conduction is reduced to $261 \text{ kcal h}^{-1} \text{ m}^{-1}$. A foam rubber lining reduces heat conduction to 17 to $143 \text{ kcal h}^{-1} \text{ m}^{-1}$, depending on the quality of the material and the thickness of the lining. A vacuum jacket or a powder-filled vacuum jacket would reduce the heat losses to 2.3 to $2.7 \text{ kcal h}^{-1} \text{ m}^{-1}$ [467].

A typical LOX tanking system, one which was developed for launching ATLAS ICBMs within the very short advance warning time, is described in [433], but is now only of historical interest. At the time when this system was designed, there were no LOX pumps available with the necessary capacity. The state of technology at that time was a pump with a capacity of 1900 L min^{-1} . The required rate of transfer was 19000 L min^{-1} and would have required the simultaneous use of 10 of these pumps. Thus, the designers chose pressurized transfer. The oxygen pressurant was stored at 160 atm gauge and reduced to 6.8 atm gauge (100 psig) before pressurizing the 106 m^3 capacity LOX tank. This tank was well insulated and had boil-off losses of only 0.25%/day. The feed pressure was 6.8 atm gauge (100 psig) and the pressure drop was less than 3.4 atm (50 psid). The flow rate of 19000 L was achieved only after all components had cooled to the temperature of LOX. The main duct was made from stainless steel, had a diameter of 30.4 cm (12 in.) and a wall thickness of 3.6 mm. It was not insulated with foam because during the short time of operation, the heat capacity of the insulating material would have caused higher evaporation losses than those caused by frost build-up and convection to the environment. The filter that was intended to retain ice crystals and other particulate matter was rated at $40 \mu\text{m}$.

In addition to the main duct, which was used to fill the LOX tank to only 90–95% of its capacity, a smaller line was used for topping off the tank and maintaining its LOX level during the countdown and extended high alert time. LOX used for topping off was precooled by passing it through a bath of LN_2 to allow more accurate metering (without bubbles) and maintain the filling level in the missile to within $\pm 0.5\%$ of the intended value.

Most of the stationary rocket engine development and performance tests use pressurized propellant feed systems for reasons of economy and expediency. Because of the need for obtaining accurate flow records, many pressurized cryogenic LOX systems are placed in LN_2 baths. If both the propellant tank and flow lines are covered by such a bath, more precise knowledge of the cryogenic fluid density is obtained and a two-phase flow through orifices or flow meters is eliminated. The density of LOX can vary by 1% for a temperature change of 1.3 K (2.3°F), and the uncertainty due to two-phase flow through an orifice cannot now be estimated [468].

In the meantime, LOX pump development has made significant progress and now pumps are available from cryogenic supply houses. Two of the pumps together can handle a flow rate of 22700 L/min [469].

Various components (valves, filters, flow meters) will cause pressure drop in the transfer line. Pressure drop during transfer of LOX and other cryogenic fluids can be calculated using the method described in reference [470].

9.4 Net Positive Suction Head in LOX Tanks

In a flight vehicle, the pressure in the LOX tank and the **Net Positive Suction Head** (NPSH) at the pump inlet must be maintained despite diminishing hydrostatic head throughout the flight of the stage in order to prevent cavitation. In many cases, it would require an excessive amount of compressed helium or compressed oxygen to maintain pressure in the increasing ullage space. In the SATURN-V S-IC booster stage some of the LOX was diverted through a heat exchanger/vaporizer and warm gas was used to pressurize the tank during flight [471, 472].

9.5 Transfer Lines and Piping

Transfer lines and piping are used either outside the flight vehicle on the ground or inside the flight vehicle. In the case of the Space Shuttle, transfer lines were used between different parts of the vehicle. If inside the flight vehicle, lightweight design is a requirement. For cryogenic service, the transfer lines may be insulated to reduce heat losses or if in use for only a short time, may be exposed to the atmosphere without external insulation. Design considerations for cryogenic transfer lines and stationary piping are different from the design for conveyance systems for room temperature liquids [473].

During cooldown, the worst problem happens if the top of a partially filled pipeline where the gas flows cools down at a different rate from the bottom of the pipeline where the liquid flows. Temperature differences cause the pipeline to bow and may tear it apart. In conventional piping systems, enough uniform thermal cool-down flexibility is obtainable by the use of expansion loops. Uniform thermal cool-down occurs when the pipe is full of liquid and the entire pipeline has cooled to liquid temperature. In the case of rocket fueling systems employing cryogenic transfer lines, space and weight limitations may preclude the use of expansion loops or bellows for achieving flexibility. In addition, this uninsulated thin-walled transfer piping is subject to temperature gradients of a scale not usually encountered in process piping systems and because of these temperature gradients the phenomenon of pipeline bowing occurs [474]. Bowing is the tendency of the centerline of the pipe to be deformed into an arc.

A numerical simulation for the steady flow and precooling and filling process of liquid hydrogen/LOX feed lines by using a method of CFD and numerical heat transmission included two aspects: **(1)** For compressibility of liquid hydrogen/LOX, the SIMPLE method has been used to calculate 2-D steady state transport, and a finite difference method has been adopted to simulate 1-D heat transmission of the high vacuum multi-layer adiabatic structure [475]. Flow field, temperature field and heat transmission have been calculated and analyzed in order to optimize existing propellant lines and reduce the loss of low temperature propellants. **(2)** Using a fluid dynamics

model of 1-D homogeneous equilibrium state and heat transfer model covering main heat transfer work conditions in a precooling process, considering compressibility of low temperature propellants, a pipe flow formula was calculated by a finite volume method and 1-D non-steady state heat conduction formula of the internal pipe wall. The precooling process of the test-bed system of a rocket engine was calculated, simulated and experimental results were analyzed, and the results provided support that the engine system could be improved.

9.6 Geysering in Vertical Lines

In a 1-g environment on the ground, if LOX remains standing in vertical sections of transfer lines, it will slowly warm up. Lower sections of the LOX volume will boil later due to the hydrostatic pressure of the liquid above it; however, once the stratification is disturbed and the layers with different temperatures become mixed, an effect called “geysering” causes sudden pressure rises and slugs of liquid to be ejected from the pipeline. This is like the periodic eruptions of hot springs in geothermally active areas. For a cryogenic fluid storage and transfer system, geysering must be avoided to prevent pressure surges and unpredictable flow rates, making accurate fluid metering impossible [476, 477]. In a flight vehicle tank, geysering can have catastrophic consequences. The LOX intake duct of the oxidizer pump might momentarily contain mixtures of liquid and gas which leads to cavitation in the suction area of the pump. The LOX tank of the SATURN-V S-IC stage used a steady flow of helium gas bubbled through and injected at the bottom of the tank to recirculate the LOX and prevent stratification and geysering [478].

Geysering can occur with all cryogenic fluids, but for rocket applications it is most frequently observed with LOX and LH_2 .

9.7 Zero-g Cryogenic Propellant Transfer for Retanking in Orbit

It is difficult enough to achieve refueling of satellites and space stations in orbit with storable, non-cryogenic propellants. This technology required more than 50 years of development before the first robotic demonstration propellant transfers in orbit were achieved. Transfer of cryogenic propellants in orbit has not yet been demonstrated but will be required for future space missions and orbital propellant depots [479, 480]. Cryogenic fluid transfer would allow the reuse of vehicles already in orbit, thus reducing launch lift mass, and extend the range of missions. Orbital tanking (fueling) stations, propellant depots, are still a thing of the future. While storable propellants can be transferred under zero-g conditions between diaphragm or bladder tanks, no such tanks exist for cryogenic propellants because most diaphragm or bladder materials are brittle at cryogenic temperatures.

There was also the plan to scavenge unused cryogenic propellants from Space Shuttle external tanks in orbit before those near-empty tanks were sent to a destructive re-entry. Such scavenging would depend on complete mastering the techniques of cryogenic propellant transfer under zero-g conditions; however, in practice, the tanks were usually jettisoned before the Space Transportation System (STS, Space Shuttle) orbiter reached orbital speeds.

10 Cleaning of LOX Equipment

Equipment intended to be filled with LOX must be carefully cleaned to prevent accidental ignition and particulate contamination. Similar cleaning specifications apply to both GOX and LOX equipment.

One section in an ASTM Manual describes cleaning requirements for LOX equipment [481]. The oxygen system cleaning specifications drawn from 23 industrial and government sources were compared along with cleaning processes employed for meeting these specifications and recommended post-cleaning inspection procedures for establishing the cleanliness achieved [482].

11 Hazards in Handling of LOX

Air Force Manual (AFMAN) 20-203V2, Chemical Rocket/Propellant Hazards (formerly designated as Air Force Manual (AFM) 161-30) contains a chapter on handling of LOX. NASA and ASTM have issued a series of LOX safety manuals [483–488].

11.1 Protective Clothing and Tools

Personnel handling propellants in the vicinity of LOX operations should wear protective suits, face mask or safety goggles, and gloves. Protective clothing for personnel handling propellants should protect against frostbite if LOX is accidentally spilled on the clothing. In addition, such clothing must be made of flameproof materials that will not burst into flames when accidentally ignited.

All components for LOX service must be thoroughly degreased. Even the skin grease from a fingerprint may be enough to initiate combustion or explosions. There are special lubricants (greases and oils) approved for LOX service (see section “Lubricants for Liquid Oxygen Systems”).

All tools for service in LOX installations should be spark-proof. Electrical service components (switches, circuit breakers) should be spark-proof. All tanks and transport containers should be grounded to prevent build-up of static electricity.

11.2 Firefighting

Fires that are sustained by LOX or evaporating oxygen are very difficult to extinguish. One must attempt to shut off the supply of oxygen as the first measure of defense. Only after the supply of oxygen has been shut off, can fires be brought under control using conventional methods of firefighting. The firefighting strategy depends on the proximity of the fire to adjacent fuel tanks at a launch site. If it involves only a building and no fuel tanks, one will allow the crew to get closer than if a fuel tank is exposed to the fire and must be cooled to prevent it getting involved in the disaster. If the temperature is high enough to involve structural metals (aluminum, iron), the combustion temperature will be extremely high and the fire becomes even more difficult to extinguish because molten aluminum and iron will react chemically with water, evolving hydrogen gas. The devastation caused by a fire in a tank farm is illustrated in Figure 42. This fire started from an unidentified cause in a pipe section between the storage tank and the tanker truck being filled with LOX and propagated rapidly through the entire facility, destroying several tank cars and trucks.

Figure 42: Destruction in a LOX transfer facility caused by a LOX-sustained fire (reproduced from [359] with permission from AIAA)

11.3 Liquid Oxygen Spills

If LOX and liquid fuels have leaked at the same time, forming a mixture of oxygen and frozen fuels, this mixture constitutes an extreme explosive hazard. It can be initiated by sparks, flame, impact or friction. In such a case all potential sources of ignition must be removed, and it is best to wait from a safe distance until all LOX has evaporated. If the leaked fuel is water soluble (ethanol, hydrazine, unsymmetrical dimethylhydrazine, UDMH), one can then dilute the puddle with enough water to bring the concentration below the flash point.

The evaporation rates of LOX spilled onto the ground surface were measured in laboratory tests [489]. To simulate the ground, concrete, dry sand, and wet sand layers were used in a vacuum-insulated transparent cylindrical glass vessel. Based on the temperature variations within the layer and detailed observation through the side of the vessel, the heat transfer modes controlling the evaporation phenomenon were revealed. When a wet sand layer was used, the LOX did not soak into the layer, because the frozen layer of water between the liquid and the sand layer acted as a barrier. When a concrete layer was used, the liquid vaporized above the layer. In these cases, the evaporation rates were inversely proportional to the square root of the time, except in the early stage just after the start of evaporation. This relationship could be predicted by a simple calculation of heat conduction within the layer. When a dry sand layer was used, LOX was observed to vaporize while constantly soaking into and rolling up the upper layer of the sand pit. In this case, the evaporation rate was determined simply by the velocity of liquid penetration downward through the sand layer.

11.4 Gelled Cryogenic Liquid Oxygen Mixtures

Gelled propellants have been tested typically only for storable propellants. It would be much more difficult to find suitable gelling agents for cryogenic propellants. One may want to gel LOX in order to suspend finely divided additive particles to enhance the performance or to make it hypergolic with other fuels; however, many of those mixtures with combustible gelling agents may be more useful as explosives instead of rocket propellants.

11.5 Explosive and Fire Hazards of Liquid Oxygen

In the wake of two gaseous oxygen supported fires, one on 27 January 1967 in the Apollo-1 capsule during ground rehearsals and one in an animal research facility, each with multiple fatalities, NASA expanded the fire safety testing for all materials, non-metallic and metallic, in oxygen-enriched atmospheres and developed standardized test methods to evaluate the acceptability of materials for future spacecraft. In addi-

tion, numerous accidents in hospitals where oxygen-breathing patients caught on fire have heightened the awareness of oxygen-sustained fire hazards.

Although most of these test methods were designed for testing materials in GOX, some can be adapted for tests in LOX and some have the capability to test both.

All oxygen systems on the ground should be designed and operated in accordance with ASTM Standards for Fire Hazards in Oxygen Systems [490] and ASTM Manual MNL36-2ND [481]. This heavily revised new edition provides a practical set of guidelines for safe oxygen system design, storage, handling, and usage. This manual begins with an overview of the basic oxygen safety guidelines, followed by a description of oxygen system ignition mechanisms and materials information related to flammability, ignition, and combustion. Next, the process for performing an oxygen compatibility assessment is described, followed by design principles, which are fundamental to the safe use of oxygen. Cleaning for oxygen service is the next topic, followed by various operational issues, such as storage facility design, transportation and transfer, equipment hazards, and emergency procedures. See also [484–487].

An *Acceptability Index* AI has been defined as

$$AI = (OI)^2 \frac{T}{C}$$

where AI is the acceptability index in arbitrary units, OI is the oxygen index, the lowest oxygen volume-% concentration in nitrogen which will sustain equilibrium (upward?) combustion of the material, T is the autoignition temperature in 100% O_2 and C is the heat of combustion at 20 atm in pure oxygen. The AI is a means for comparing different candidate materials [491].

The industry is well-advised to maintain a complete and up to date record of accidents with LOX to eliminate incompatible materials, share lessons learned, and develop safe handling practices [492].

11.6 Accidental Ignition in Oxygen

There are many types of stimuli that can lead to accidental ignition of materials in GOX or LOX. Cleanliness and elimination of contaminants is imperative with all oxygen systems. Accidental ignition in the Apollo space capsule in an oxygen atmosphere led to the death of three astronauts.

The ignition of non-metallic materials by electric arc and mechanical impact and by a resonant process involving repeated shock waves has been demonstrated and ignitions due to the rapid rupture of metal films and diaphragms were reviewed [493]. Burning rate studies of three non-metallic materials in oxygen-enriched environments were measured. Combustion under zero gravity was compared to combustion under 1-g gravity.

11.6.1 Metal Combustion in Oxygen

Starting in 1982, the ASTM Committee G-4 on Compatibility and Sensitivity of Materials in Oxygen-Enriched Atmospheres has organized a series of conferences and published a series of conference proceedings with constitute a rich source of information on combustion of metals and other materials in oxygen. References leading to a few of the conference proceedings are listed here: [494–499]. The ASTM Committee G-4 on Compatibility and Sensitivity of Materials in Oxygen-Enriched Atmospheres has issued a standard test method for compatibility of materials with LOX (impact sensitivity threshold and pass-fail techniques) [500] which has gone through several revisions during the past 30 years [501]. This method uses a modified Army Ballistic Missile Agency (ABMA) type impact tester. According to this test method, 20 separate samples of the material submerged in LOX are subjected to 98 J (72 ft · lb_f) impact energy delivered through a 12.7-mm (1/2-in.) diameter contact. More than one indication of sensitivity is cause for immediate rejection. A single explosion, flash, or other indication of sensitivity during the initial series of 20 tests requires that an additional 40 samples be tested without incident to ensure acceptability of the material. The threshold values are determined by this test method at ambient pressure. The sensitivity of materials to mechanical impact is known to increase with increasing pressure. Since most LOX systems operate at pressures above ambient conditions, some consideration should be given to increased sensitivity and reactivity of materials at higher pressure when selecting materials for use in pressurized system.

In many accidents a less compatible polymer was the source of ignition which then spread to adjacent metals. Excellent summaries on combustion of metals in oxygen-enriched atmospheres were published in [502–504]. “*Promoted ignition-combustion*” is a term which has been used to describe a situation where a substance with poor oxygen compatibility ignites and supports the combustion of a more combustion-resistant adjacent material [505]. This can happen in GOX or in LOX in contact with aluminum, carbon steel, stainless steels, or titanium alloys.

The conditions for ignition of compact specimens and foils made of iron, nickel, copper, and stainless steel in oxygen under pressures of 0.1–70 MPa were studied and modeled with the use of modified equations and dimensionless parameters of the heat theory of ignition of metal particles. Calculation results were compared with experimental data [506]. See also [507–509].

11.6.1.1 Aluminum Combustion in Oxygen

The use of aluminum alloys as a structural material for oxygen equipment has made it necessary to examine the conditions of combustion propagation in relation to the geometry of the part, the oxygen pressure, and the thermophysical parameters of the alloy [510]. It was experimentally established that the burning rates of aluminum wire 1 and 2 mm in diameter in pure oxygen increased with an increase in oxygen pressure in accordance with the equation $u \sim p^{0.5}$ in the pressure intervals $0.05 < p < 1.6$ MPa and $3.2 < p < 10.0$ MPa; however, in the intervals $1.6 < p < 3.2$ MPa and $p > 0.05$ MPa the

burning rates decreased as the pressure rose. In order to establish the dependence of the burning rate u on the oxygen pressure p and the specimen diameter d , cylindrical specimens of the aluminum alloys AMts (Mn 1.0–1.6%) and AMg-6 (Mg 5.8–6.8%, Mn 0.5–0.8%, Soviet standard GOST 4784-65) 300 mm long and 2–6 mm in diameter were tested in a constant-pressure bomb in the absence of an external oxygen flow. The initial temperature of the pure oxygen was 18 °C. The specimens were ignited at one end by an ignition coil. The time taken by the combustion zone to travel a length of 120 mm along the specimen was measured and recorded by means of a memory tube oscillograph.

Aluminum alloys are widely used in the construction of equipment found in rocket propulsion applications. The promoted-ignition combustion behavior of aluminum alloy 5183 was studied in oxygen-nitrogen gas mixtures over the pressure range of 0.1–20.8 MPa with oxygen purities ranging from 40 to 99.7% using 3-mm diameter rods (Figure 43) [502]. For comparison, utilizing the same test method and specimen size, the promoted ignition-combustion resistance of a commercially pure titanium alloy and Nb-55Ti titanium alloy was studied in oxygen-nitrogen mixtures with oxygen purities ranging from 30 to 80% oxygen at pressures up to 1.5 MPa.

The promoted ignition, flame spreading and combustion phenomena of aluminum tubing filled with LOX, surrounded by a shell of GOX, were systematically

Figure 43: Flammability boundaries between burn and no burn zones for aluminum alloy 5183 (reprinted with permission from *Flammability and Sensitivity of Materials in Oxygen-Enriched Atmospheres: Seventh Volume*, © 1995 ASTM International)

observed and recorded with over 70 promoted combustion tests [511, 512]. The aluminum 3003 tube samples used were 30.48 cm long and 3.175 mm outer diameter. Two different wall thicknesses (0.254 and 0.356 mm) were used for comparison testing. Parameters studied included the tube and shell side pressures, LOX and GOX purities, tube sample wall thickness and the igniter location. Results from high-speed cinematography indicated that under certain operating conditions, a transition from a “normal” (much slower) burning mode to an extremely rapid and violent burning mode can occur. The “violent energy release,” or VER burning mode, is characterized by extremely high flame spreading rates (1–2 orders of magnitude faster than the flame propagation rate in a pure GOX environment), a high luminosity flame zone, and a very rapid rate of heat release. The rapid onset of transition to VER and the striking transformation between normal and VER burning modes can be seen on some of the high-speed photographs taken. It is believed that the onset of transition to VER is triggered by a high rate of convective mass flux of oxygen to the reaction zone, caused by the density change from liquid to gas phase of oxygen. The high tube-side oxygen flow velocity lowers the diffusion resistance of oxygen to the reaction zone and atomizes the molten aluminum near the reaction region, removing oxide accumulations and exposing fresh aluminum to direct chemical attack. This process then results in greatly enhanced homogeneous and heterogeneous reaction rates. The burning rate of 0.356 mm wall thickness Al-3003 tubing in gaseous oxygen at 27.57 MPa was 279 mm/s [513, 514]. Contaminants will facilitate ignition of aluminum in LOX [515]. The results of impact sensitivity tests depend on the type of striker pin used. See also reference: [516].

11.6.1.2 Steel Combustion in Oxygen

Steel will burn in GOX under certain conditions [517]. The experiments were carried out using cylindrical metal samples with a diameter of 3 mm made of SVO8A wire (a low-carbon steel with a carbon content of less than 0.1%) and SVO4Kh19N9 (Cr 19%, Ni 9%, C < 0.04%), as well as turned samples of 2Kh13 (Cr 13%, C 0.2–0.3%). The apparatus permitted setting up flow velocities up to 1.5 m/s. Ignition of the samples, oriented horizontally, was carried out from one end using an ignition coil. The direction of the oxygen flow was concurrent with the direction of propagation of the combustion. The initial temperature of the oxygen was equal to 291 K (18 °C). The experimental results are presented in Figure 44 for two different steels.

As is evident from Figure 44, the limiting pressure at which the combustion propagated over the sample, p_p decreased sharply even at small flow velocities U , and in the region $U = 0.08\text{--}0.2\text{ m/s}$ can be described by the relationship $p_p = 0.8U^{-1}$ (p_p in atm and U in m/s). At $U > 0.1\text{ m/s}$, there are substantial deviations from this dependence. With $U < 0.03\text{ m/s}$, i.e., at flow rates comparable to the rates of propagation of the combustion, the values of p_p practically do not change and at $U = 0$ are equal to 28 atm. At $U > 0.03\text{ m/s}$, the rates of propagation of the combustion rise. The rates of propagation of combustion along an SVO8A wire with $pU < 2.2$ obey the dependence

Figure 44: Combustible range of steel in gaseous oxygen (republished and modified from [517], with permission of © 1972 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

$U = 0.61 \times 10^{-2} (Up)^{0.5}$, while, at $pU > 2.2$, there are deviations from this dependence and with $U < 0.03$ m/s, U may take on values lower than in the absence of a flow.

It was shown that cylindrical iron and carbon steel specimens of diameters 1.5 and 3 mm ignited in oxygen at the moment the oxide film lost its protective properties, supposedly, as a result of melting of its main component (FeO) at 1644 K [518]. The ignition temperature did not depend on the oxygen pressure (in the range 0.2–20 MPa). The ignition was preceded by substantial (about 100 K) self-heating of a specimen owing to the heat released upon oxidation of the metal. A carbon-steel foil ignited in oxygen (0.14–0.6 MPa) according to the Semenov-Frank-Kamenetskii mechanism at an initial surface temperature not lower than 1233 K.

11.6.1.3 Titanium Combustion in Oxygen

Titanium alloys are preferred materials of construction in certain environments where severe corrosion is of concern and where lightweight tanks would improve the mass ratio of the rocket or satellite; however, there are known instances where they have proven to be incompatible with oxidizers, such as LOX, GOX, red fuming nitric acid (RFNA), and “red” dinitrogen tetroxide. Recent developments in titanium alloys have been oriented towards improvement of their ignition resistance in oxygen-enriched environments for specific applications.

Titanium can be quite reactive in oxygen environments. Besides being widely used in storable rocket propellant tanks, titanium is a preferred material of construction for numerous chemical process industry applications where corrosion resistance in hostile environments is required. Hazardous waste disposal via supercritical wet

oxidation and pressure oxidation processes used in gold mining are examples for the use of high-pressure titanium-clad reactors. It was reported that by alloying titanium with niobium, the pyrophoricity can be reduced to give a larger safety margin for autoclaves used in the chemical industry.

Titanium and its alloys are widely used in aerospace industry where the metal's low density, high-specific strength, and corrosion resistance properties are required. Titanium and its alloys are used in jet engines, airframes, and in oxidizing sulfuric acid environments present in sulfide pressure-leaching operations (pressure oxidation autoclave.). Titanium has been considered for use in oxygen-enriched environments, such as space suit applications; however, like most metals and alloys, titanium will burn in oxygen-enriched environments.

Early work conducted in 1960–1961 under a USAF contract demonstrated that titanium would be consumed by violent reactions when a freshly formed titanium surface was exposed to oxygen [286, 519]. The freshly formed surface was formed by pulling tensile specimens in the presence of oxygen. Reactivity was demonstrated in a temperature range from -190°F to room temperature. One pulled sample of pure titanium did not react at 515 kPa (60 psig) but did react at 620 kPa (75 psig) in the room temperature tests in 100% oxygen. This data demonstrated that this ignition test approach is much less severe than the promoted ignition combustion technique used in later investigations in which the sample was preheated by resistance heating and the sample tip temperature was raised to the melting point.

It was reported that titanium reacted not only in a 50% oxygen/50% carbon dioxide mixture at a temperature of 1033 K (1400°F), under 2.06 MPa (285 psig) pressure, but also in 100% carbon dioxide where a reaction occurred at 1700 K (2600°F) at 2.06 MPa (285 psig) [520]. Tubular test sections of stainless steel, cobalt, and nickel alloys, besides aluminum, copper, and titanium were resistance heated in controlled atmospheres of oxygen, carbon dioxide and an equal mixture of these gases. Motion picture coverage showed the manner in which the tubes heated and failed. Stainless steel and cobalt alloys ignited within the melting point range of each material. Nickel alloys did not ignite until the melting point was reached.

Testing commercially pure titanium at low pressures (0.14 MPa) and at 70% gaseous oxygen resulted in complete combustion of the test samples [502]. Testing at 60 and 50% O_2 identified the pressure thresholds at which combustion occurred as 0.17 and 0.27 MPa, respectively (Figure 45). At 40%, combustion did not occur at 0.79 MPa but did occur at 1.48 MPa. Finally, at 30% oxygen purity, the samples did not burn even at a pressure of 1.48 MPa. Figure 45 shows a summary of the promoted ignition-combustion data for titanium alloy Nb-55Ti. At oxygen purities in excess of 60%, this alloy is flammable at pressures down to the limit of the flow test apparatus although slightly less than the commercially pure titanium alloy. At the 60% purity level, it was not flammable at pressures up to 0.27 MPa. Reducing the oxygen purity down to 50% increased the non-flammable zone to 0.79 MPa. At 30 and 40% oxygen purity, the Nb-45Ti was non-flammable up to the maximum test pressure of 1.48 MPa.

Figure 45: Flammability boundaries between burn and no burn zones for titanium and niobium/55 titanium alloy (reprinted, with permission from *Flammability and Sensitivity of Materials in Oxygen-Enriched Atmospheres: Seventh Volume*, © 1995 ASTM International)

The ignition propensity of titanium was determined by frictional ignition testing and the combustibility determined by promoted combustion testing [521]. Results indicated that the pressure $\times$ volume (PV) energy per unit surface area product required for ignition by friction was $0.0035 \times 10^3 \text{ W/m}^2$ ($0.01 \times 10^6 \text{ psi ft/min}$) and in 100% oxygen titanium is combustible at pressures as low as 13.8 kPa (2 psia).

The *Frictional Heating Test* apparatus consisted of a high-pressure test chamber, an electrical motor and transmission assembly, and a pneumatic actuation cylinder [522, 523]. The high-pressure test chamber, fabricated from Monel 400, consisted of a cylindrical chamber with a replaceable nickel sleeve. The chamber contained a rotating shaft that extended through the chamber by a series of bearings and seals. The shaft was connected at one end to a drive motor and transmission assembly that could rotate the shaft up to 30000 rpm. The other end of the shaft was connected to a pneumatically actuated cylinder capable of applying up to 4450 N (1000 lbf) normal load on the test specimens. The rotating test specimen was mounted on the shaft, and the stationary test specimen was affixed to the test chamber. Tests were conducted in GOX at 6.9 MPa (1000 psia) and 17000 rpm while increasing the load at a rate of 35 N/s (7.8 lb ft/s) until ignition occurred.

In addition to the frictional ignition test, the metals were also tested in a *Promoted Combustion Test*. The promoted combustion test system consisted of a cylindrical stainless steel chamber with an internal volume of approximately 740 cm^3 (45 cu. in.). The chamber could be pressurized to 68.9 MPa (10000 psia) and had a copper

liner and a copper base plate to protect it from the burning metal. The test specimen was ignited with an aluminum or magnesium wire wad. Titanium alloy Ti-6Al-4V, was easily ignited by friction. Ti-6Al-4V was tested at 2250, 4500, and 6750 rpm, while Al-6061 and Inconel MA 754 were tested at 17000 rpm. Ti-6Al-4V samples tested in GOX tended to friction weld at 2250 rpm.

Diaphragms of thin titanium and aluminum alloy stainless steel sheet have been pressurized with liquid or gaseous oxygen and gaseous nitrogen, and subjected to impact from a high velocity, small steel projectile [524]. Titanium alloys burned in the oxygen environment but did not burn in either the sea level air environment or pure nitrogen at pressures up to 414 kPa (60 psi). Although stainless steel and aluminum are relatively unreactive in the oxygen environment, these metals will burn sympathetically when placed in contact with burning titanium.

Once ignited, the combustion of solid titanium metal in oxygen may extinguish under a crust of titanium oxide. The combustion of bulk titanium in oxygen at sea level atmospheric pressure was studied using laser ignition, high-speed color cinematography, time and space resolved spectra in the visible region, metallography of specimens quenched in argon gas, XRD, and chemical product analyses [525]. The results indicated that an initial vapor phase reaction immediately adjacent to the molten surface starts rapidly, but as the oxygen uptake progressed, the evaporation rate slowed down. The accumulation of the various soluble oxides soon drove the reaction zone below the surface where gas formation caused boiling and ejection of particles. The build-up of a titanium oxide coating may cut off the oxygen supply and cause the reaction to cease.

The flammability of commercially pure (CP) titanium rods in oxygen-enriched atmospheres as a function of diameter and test gas pressure was determined [526]. Test samples of varying diameters were ignited at the bottom and burned upward in gaseous 70% O₂/balance N₂ and in 99.5+% O₂ atmospheres at various pressures. Test samples were 15.2-cm (6.0-in.) long rods having diameters of 0.8 mm (1/32 in.), 1.6 mm (1/16 in.), 3.2 mm (1/8 in.), 4.8 mm (3/16 in.), and 6.4 mm (1/4 in.). The burning rate of each ignited sample was determined by observing the apparent regression rate of the melting interface of the burning samples. The burning rate increased with decreasing test sample diameter and with increasing test gas pressure and oxygen concentration. The regression rate of the melting interface (burning rate, RRMI) was plotted as a function of test gas pressure and a least squares curve fit through the burning rate data yielded a logarithmic curve which describes the burning rate as follows:

$$\text{RRMI} = 1.1135 \ln(A)^{-2.8163}$$

where RRMI is the regression rate of the melting interface (burning rate) in in./s and A is the test sample cross-sectional area in in.².

11.6.1.4 Nickel Alloy Combustion in Oxygen

It was found that compact samples of nickel and its alloys heated in “cold” (323 K) and “hot” (≤ 1573 K) oxygen ignited only at temperatures exceeding the melting point of the materials [527]. The ignition temperature was independent of the oxygen pressure up to 70 MPa. It was suggested that the drop in the ignition temperature of alloys with rising oxygen pressure reported in other papers is related to systematic errors in measuring the surface temperature of the samples.

11.6.2 Refractory Alloys in Oxidizing Environments

Turbine blades driven by lean-operating gas generators and pump impellers are exposed to extreme conditions that may lead to ignition of the metals. Turbine blades and pump impellers are typically made from oxidation-resistant superalloys. Nevertheless, several of these metals were tested [528]. In the particle impact tests, nickel 200, Monel 400, and silicon carbide were the most resistant to ignition; Monel K-500 and zirconium copper were slightly less resistant to ignition; and Hastelloy X, Invar 36, and stainless steel 316 were the least resistant to ignition. In frictional heating tests of pairs of like materials, the ranking was generally upheld, with the materials ranked in order of decreasing resistance to ignition as follows: nickel 200, Inconel 600, Monel 400, Monel K-500, Hastelloy X, Invar 36, and stainless steel 316.

11.7 Drop Weight Impact and Shock Sensitivity of Liquid Oxygen/Contaminant Mixtures

In accordance with ASTM test procedure D2512-95 [529], a sample of the test material is placed in a specimen cup, precooled and covered with liquid oxygen and placed in the cup holder located in the anvil region assembly of the impact tester. A precooled striker pin is then centered in the cup. The plummet is dropped from selected heights onto the pin, which transmits the energy to the test specimen. Observation for any reaction is made and the liquid oxygen impact sensitivity of the test material is noted. Drop tests are continued using a fresh specimen cup and striker pin for each drop, until the threshold value is achieved. A series of drop tests are conducted at an energy level of 98 J (72 ft-lb_f) or as specified for the pass-fail tests and a 50% point calculated by the Bruceton up-and-down method. This test apparatus is similar to the BAM apparatus illustrated in Figure 35.

Mixtures of LOX and organic compounds can have friction and impact sensitivity properties similar to those of the much-feared nitroglycerin [253].

The impact sensitivity of organic compounds in LOX was tested with a modified ABMA drop-weight tester [530]. For 18 of the 24 compounds tested, there was a correlation between the flash point in air and the impact sensitivity in mixtures with LOX. See also reference [531].

A study was conducted to evaluate the repeatability of the LOX mechanical impact test used by NASA to screen materials for oxygen service (NHB 8060.1B Test 12 Part 1, which is based on the ASTM method) [276, 532]. Four materials were tested: Teflon, Vespel SP-21, Viton A, and Nylon 6/6. Each test material was subjected to several series of tests that were conducted at different impact energy levels. The results showed that the variability from series to series in the reaction threshold energy level was within the precision statement of the ASTM method; however, this precision was considerably broader than the reaction threshold implied by the NHB 8060.1B test criteria.

The impact ignition mechanism in LOX is a real combustion ignition mechanism that needs to be understood in the design of oxygen systems. The use of test data from this test method has been questioned due to the lack of a clear method of application of the data and variability found between tests, material batches, and facilities [533]. A large database has accumulated over several years, but data are not always consistent. Testing was performed to determine the statistical nature of the test procedure to help establish sample size guidelines for material characterization. The common method of determining a pass/fail criterion based on either light emission or sound report or material charring was questioned.

In addition to impact testing of mixtures with LOX [534], similar test methods have been applied to impact or adiabatic compression testing of materials in gaseous oxygen. NASA JSC and Southwest Research Institute have developed a GOX drop weight impact sensitivity test method [535–538].

Adiabatic compression testing of components in GOX is a test method that is utilized worldwide and is commonly required to qualify a component for ignition tolerance under its intended service [539]. This testing is required by many industrial standards organizations and government agencies. Ignition may occur during rapid pressure surges.

There may be a correlation between dynamic pneumatic adiabatic compression ignition pressure ratios per ASTM G 74 and the autoignition temperature of polymeric materials in a static test [540]. The data obtained on five polymers resulted in a strong correlation between the 50% reactivity level and the AIT of polymers, indicating similar ignition mechanisms.

11.8 Bullet Impact Sensitivity of Liquid Oxygen

A .50 caliber incendiary bullet was fired into a titanium LOX tank [289, 541]. A huge flash was observed, and a violent reaction occurred, resulting in fragmentation of the vessel. Fusion and burning were noted on the fracture surfaces of some of the pieces. Similar tanks of type 304L stainless steel apparently failed to react and did not shatter unless they were faulty or had defects at the grain boundaries.

The nature of the problem incurred by meteoroid impacts in space flight is ill-defined. Although much work has been reported in this field, there still exists a very high degree of uncertainty of predictions of meteoroid impacts and their effects on space vehicles. The results of the previous puncture tests strongly indicated that penetration of titanium tanks containing LOX by a single meteoroid encountered in space flight could result in a catastrophe. Consequently, it was decided to investigate the behavior of titanium diaphragms, pressurized with LOX, upon simulated meteoroid punctures. In one test series, 0.1–0.2-g steel projectiles were fired through air at velocities from 2.77 to 4.85 km/s (9100–15900 ft/s) into titanium, aluminum, and stainless-steel diaphragms, internally pressurized with LOX. Diaphragms of thin titanium and aluminum alloy stainless steel sheet have been pressurized with LOX or GOX and gaseous nitrogen, and subjected to impact from a high velocity small steel projectile [287, 542]. Titanium alloys burned in the oxygen environment but did not burn in either the sea level air environment or pure nitrogen at pressures up to 414 kPa (60 psi). Although stainless steel and aluminum are relatively unreactive in the oxygen environment, these metals will burn sympathetically when placed in contact with burning titanium. In this study, two diaphragms were tested simultaneously by use as front and back closures for a cylinder aligned with the path of the projectile. Using titanium discs, the back diaphragm ignited and burnt violently 15 times in 16 tests. Test conditions included both the Ti-5Al-2.5Sn alloy and the Ti-6Al-4V alloy, in thicknesses of 0.63, 0.4, and 0.35 mm (0.025, 0.016, and 0.014 in.), GOX at room temperature or LOX, and pressures of 138 and 414 kPa (gauge) (20 and 60 psig). The front diaphragm reacted less often, but still reacted in over one half of the tests. Control tests using 414 kPa (gauge = 60 psig) GN_2 or zero psig air with titanium diaphragms produced no reactions. Eight trials with 0.4-mm (0.016-in.) thick 2024-T3 aluminum discs and seven trials with 0.25-mm (0.010-in.) thick 301-XFH stainless steel also failed to react; however, slight oxidation was noted around some of the penetrations in aluminum. It was also investigated whether sandwiching of the titanium between aluminum or stainless steel plates would diminish the reactivity, but the titanium reaction ignited the aluminum or stainless steel, which also burnt violently. Results from these sandwich tests show that cladding titanium with aluminum or stainless steel will not prevent Ti/LOX reactions.

11.8.1 Cap Sensitivity of Liquid Oxygen/Contaminant Mixtures

In one test, 37 L ethanol and 37 L LOX were mixed and initiated by a detonator. The resulting explosion was equivalent to that of 25–50 kg TNT [543].

The explosive limits and energy output of LOX/liquid methane system were determined at 90 K for mixtures containing 6–80 mol-% or 3–67 mass-% liquid methane [143]. The methane used for these experiments had a composition of 96.77% methane and 3.37% ethane. The charge was confined in an iron can (5 cm = 2 in. in outside diameter, 5.7–9.5 cm high, 0.25 mm = 0.01-in. wall thickness) filled with 100 g of the mixture

and initiated by means of Primacord and a No. 6 electric blasting cap. When the charge was detonated on the 4.8 mm (3/16 in.) thick steel plate, a hole may be punctured into the steel plate, or the steel plate may be ruptured, bent downward, or only dented, depending on the brisance of the explosive. The lower limit of the LOX/liquid methane mixtures was between 3 and 6 mass-% (6 and 11 mol-%) methane while the upper limit was between 30 and 67 mass-% (67 and 80 mol-%) methane. These explosive limits differ from the flammability limits of the gaseous mixtures. The measured and theoretically calculated detonation velocity of LOX/LCH₄ and GOX/GCH₄ mixtures is illustrated in Figure 46. The maximum detonation velocity occurs with stoichiometric mixtures.

Liquid oxygen/liquid methane mixtures have been proposed as cryogenic mono-propellants, but their handling safety remains in doubt [544].

Figure 46: Experimental and theoretical detonation velocities of LOX/LCH₄ and GOX/GCH₄ mixtures (reprinted and modified from [143], with permission from © 1959 American Chemical Society; permission conveyed through RightsLink)

11.8.2 Bullet Impact Sensitivity of Liquid Oxygen/Contaminant Mixtures

The sensitivity of a LOX/liquid methane mixture which had the fastest rate of detonation (33 mol-% methane and 67 mol-% oxygen) to bullet impact was tested by firing a 22-caliber, short copper bullet through a can (2 in. diameter and 4 in. high) containing the explosive liquid mixture, the nozzle of the gun being 40 feet from the mixtures [143]. In testing the sensitivity to sparks, a 1500V discharge from a 0.1 μ Farad condenser was passed through the liquid mixture, using 1–3 mm gaps. The energy discharged was 113 millijoules. Explosions were initiated in all these tests.

The sensitivity of solid oxygen + liquid hydrogen + diluent and liquid oxygen + solid hydrocarbon + diluent mixtures was investigated employing a projectile impact to determine the shock required to detonate these mixtures [545]. With no diluent, each explosive system could be initiated by a shock stimulus of 1.0–2.5 kbar. The explosive yields were such that a mass unit of cryogenic mixture was equivalent to 0.6–2.0 mass units of TNT. Large volumes of detonable, gaseous hydrogen-oxygen mixtures would result from a massive spill of LH₂-LOX. Inhibition of detonation initiation by dry powder particle additives was investigated. The powder additives produced insignificant inhibition in comparison to that produced by gaseous diluents.

11.9 Explosive Yield of Liquid Oxygen/Fuel Mixture Explosions

In case of launch pad accidents, LOX and fuels may have an opportunity to pre-mix before they are ignited by an external source of ignition. The worst-case explosive yield of such explosions has been predicted by model experiments and by calculations [546–552].

Oxygen Fluorides

Oxygen fluorides are very useful rocket propellant ingredients, both as the main oxidizer and also in small quantities to add hypergolicity to otherwise non-reactive or insufficiently reactive oxidizers. The advantage of oxygen fluorides over nitrogen fluorides is that both the fluorine and the central atom contribute to the oxidation reaction in the combustion chamber of a rocket. There are at least four known oxygen fluorides with varying fluorine contents (Table 1).

Table 1: Fluorine content of oxygen fluorides.

Compound Name	Formula	Fluorine content, mass-% F	CAS RN
Oxygen difluoride (oxygen fluoride)	F—O—F	70.36	7783-41-7
Dioxygen difluoride	F—O—O—F	54.29	7783-44-0
Trioxygen difluoride (ozone fluoride)	F—O—O—O—F	44.19	16829-28-0
Tetraoxygen difluoride	O ₄ F ₂	37.26	

The oxygen fluorides containing more than one oxygen are less stable than the lowest member of the group, oxygen difluoride. They are hypergolic with most fuels, but oxygen difluoride is hypergolic only with a few fuels. Oxygen fluorides have found the attention of rocketeers for quite some time, but no real applications have materialized in all those years [1]. At the moment, the reason for summarizing the physical and chemical properties of oxygen fluorides in this book is mostly for historical interest [2]. No stone shall be left unturned when looking for better and more energetic rocket propellants. Before starting new efforts for the development of new rocket propellants, the information gathered during past decades needs to be summarized in a systematic manner and made available to future researchers. This is the reason why fluorine and non-metallic fluorides are discussed in some detail in this book, in spite of continuing environmental and safety concerns about their use. Some of the fluorine compounds find applications in chemical lasers. Oxygen as the central atom in non-metallic fluorides has the advantage over nitrogen that it is an oxidizer in its own right and it contributes to the combustion energy released in the rocket chamber, whereas nitrogen would only be carried along as ballast. Compared to halogens, such as chlorine or bromine, oxygen as the central atom in non-metallic fluorides for rocket propellants has the advantage of a lower atomic mass, resulting in a higher exhaust velocity. Compared to elemental fluorine, oxygen difluoride, nitrogen trifluoride and tetrafluorohydrazine are relatively easy to handle because they have higher boiling points. Oxygen difluoride (OF₂) has been categorized as a “space storable” propellant.

It was discovered that hydrocarbons as fuels in rocket engines will give higher specific impulse with physical mixtures of oxygen and fluorine (FLOX) than with either oxidizer by itself. The mixture ratio of fluorine and oxygen in such physical mixtures can change with age and progressive evaporation. It would be desirable to synthesize chemical compounds in which the fluorine: oxygen atomic ratio is fixed. One such compound is oxygen difluoride (OF_2), a chemical compound that is thermally stable and maintains its fluorine: oxygen ratio indefinitely. Of all the known oxygen fluorides (OF_2 , O_2F_2 , O_3F_2 , and O_4F_2), oxygen difluoride is so far the only one that has actually been test-fired as the main oxidizer in a rocket engine. As a sideline, it should be mentioned that there is an interest in trioxygen difluoride in admixture with liquid oxygen which renders liquid oxygen (LOX) hypergolic with many common rocket fuels. This potential application will be described in a forthcoming section in this chapter.

There are several publications which deal with oxygen fluorides as a group and discuss the similarities and difference in their molecular structures and physical and chemical properties. Some of these publications are summarized in the next section.

1 Literature on Oxygen Fluorides

Soon after the discovery of the first (and most stable) oxygen fluoride, OF_2 , there was speculation that other fluorides of oxygen might form under different conditions (i.e., in absence of water) [3]. Two very good summaries of the literature on oxygen fluorides were compiled in 1963, reference [4] with 109 literature citations, and reference [5]. These two publications were good references for the first edition of a book on rocket propellants in 1968, but of course 10 times more publications have appeared in the interim that all would need to be included here if we had the space. An excellent review of oxygen fluorides and dioxygenyl salts contains 124 references [6]. Another summary on the fluorides of oxygen was published in France [7] but has not yet been translated.

Much of the original research work on oxygen fluorides other than OF_2 was done at Temple University [8].

The effort at Jet Propulsion Laboratory (JPL) in Pasadena, CA, in the 1960s to develop high-energy space-storable bipropellant combinations for challenging deep space missions with high total impulse requirements, such as those to outer planets or comets, has resulted in a series of summary publications in support of the simultaneously on-going experimental effort to bring this oxidizer closer to full-scale use [9, 10], but this oxidizer never reached flight status and only limited ground testing in rocket engines was done.

A good summary on oxygen fluorides is the “Fluorine and Oxygen” chapter in *Gmelin Handbook of Inorganic Chemistry* [11]. This chapter focuses on oxygen fluorides O_nF_2 , $n = 1-6$, oxygen fluoride radicals O_xF , $x = 1-4$, and hypofluorous acid, HOF .

It is known that all halogens, mostly chlorine and bromine, contribute to the seasonal demise of the ozone layer in the upper atmosphere of Earth. The main man-made vehicles bringing halogens to the upper atmosphere were the fluorocarbons used as

refrigerants and aerosol propellants. To a limited extent, fluorine and oxygen fluorides are also involved in ozone reactions and the formation and destruction of O—F bonds is a key step in those reactions. This is why there are many publications on the formation of $\cdot\text{OF}$ free radicals which support atmospheric chemistry but have very little to do with rocket propellants. The thermochemical properties of all oxygen fluorides and their associated free radicals that were listed in the Joint Army Navy Air Force (JANAF) thermochemical tables going all the way up to O_8F_2 have been updated by the National Institute of Standards and Technology (NIST) [12]. That publication contains an annotated bibliography (over 600 references) for all neutral oxygen fluorides which have been reported in the literature. There is a need for additional experimental and theoretical data. See also reference [13].

2 Oxygen Difluoride

At room temperature, oxygen difluoride, also known as oxygen bifluoride, OF_2 , oxygen fluoride, monooxygen difluoride, difluorine monoxide, CAS RN [7783-41-7] is a colorless gas, that condenses at $127\text{ K} = -145.3^\circ\text{C}$ forming a yellow liquid. It is very toxic and has a pungent, unpleasant odor. The name “fluorine monoxide” has occasionally been used to describe this compound as F_2O but is chemically incorrect. That name was patterned after the name for “chlorine monoxide” for Cl_2O which is more often used in this form.

As an oxidizer for rocket propellants, OF_2 has the advantage (compared to NF_3) that both the fluorine and the central atom, oxygen, act as oxidizers, as opposed to NF_3 where the central atom nitrogen is carried along as useless ballast.

2.1 Literature Summaries on Oxygen Difluoride

The most complete accumulation of OF_2 data is in the *OF₂ Handbook* released (with only limited distribution) in 1970 [14]. See also [15, 16].

2.2 Preparation of Oxygen Difluoride

Oxygen difluoride forms when fluorine gas is passed through a dilute caustic solution containing 2% KOH

The concentration of the caustic solution must be maintained constant because if the concentration is too low, the reaction proceeds too slowly. If the caustic concentration is too high, the reaction product oxygen difluoride will hydrolyze [17]. The process can be carried out as a process with continuous replacement of the caustic solution through which the F_2 is bubbled [18–20]. Adding an excess of alkali metal fluorides

to just a little water can improve the OF_2 yield from 50 to 80% [21]. In particular, CsF addition allowed optimized OF_2 production with 86% yield. NaF was less effective.

In the course of studies of the preparation of hypofluorous acid, HOF , it was observed that substantial amounts of OF_2 were always formed as a byproduct of the synthesis of HOF . It was theorized that HOF was probably involved as an intermediate in the production of OF_2 involving the reaction [22]:

Besides by reaction of fluorine with water in alkaline solutions, OF_2 can also be obtained by electrolysis of wet hydrofluoric acid. It was known for a long time that oxygen difluoride was formed as an unwanted byproduct during the fluorine production by electrolysis of KHF_2 melts when the electrolyte was not painstakingly dry. It took a while before this method was improved in a way that OF_2 became the main product and not just a byproduct. In an effort to optimize water content and current density, initial experiments were carried out in H_2F_2 that contained 1% KF as the conductivity enhancer [23–25]. Electrolysis was carried out with nickel anodes at 7.0–7.6 V in a static cell at 0–3 °C. A method was developed to monitor the water concentration in the electrolyte on-line. OF_2 , F_2 , O_2 , and O_3 were formed at the anode and were analyzed by gas chromatography (GC). The gases were passed through a cold trap at dry ice temperature and an absorption tower with dry NaF to absorb the HF vapors. When plotting the product yield and product distribution as a function of water content, it could be seen that the OF_2 yield dropped very rapidly once the water content exceeded 0.5 mol % and leveled off at a current yield of 10% for water concentrations of 5–35 mol %. The coulombic yield of OF_2 can reach 45% and is at an optimum in H_2F_2 electrolytes containing 0.5–5 mol % H_2O . The maximum current densities could be maintained at 0.5–1 mol % H_2O . Removal of ozone by adsorption on silica gel is dangerous because OF_2 and SiO_2 can react explosively.

For electrolytic generation of OF_2 from wet HF , the ohmic overvoltage at the nickel anode was determined by both potential decay and superimposed square waves [26].

Ozone is an undesirable contaminant in the production of OF_2 . The ozone content in the electrolysis products of wet HF can be determined by GC [27]. The gases are separated on a silica gel column that is temperature-programmed from 198 to 263 K (–75 to –10 °C) to minimize decomposition.

Other investigators used 10 mass-% NaF as auxiliary electrolyte and examined water contents from 1–25 mass-% and reported yields of up to 60% [28]. Electrical conductivity in the $\text{H}_2\text{F}_2/\text{H}_2\text{O}$ system goes through a maximum at 74% H_2F_2 .

Oxygen difluoride can be produced electrochemically by introducing an oxygen-containing gas into the pores of a porous anode in an electrolysis cell containing anhydrous liquid hydrogen fluoride as the electrolyte [29].

Oxygen difluoride (OF_2) in addition to O_2 and O_3 was formed by electrolysis of H_2F_2 in the range of 0.5% < H_2O < 20% beginning at a voltage of 4 V [30]. The OF_2 yield decreased with increasing water concentration and voltage. The maximum of the OF_2

formation appeared at 2% H_2O in the range between 5 and 9 V with a concentration of ~45% by volume of OF_2 in the anodic gas. Below 2% water the formation of elementary fluorine as byproduct can be observed. The formation of OF_2 depended on the formation of a black layer on the surface of the nickel anode, which was formed during an induction period. K_2NiF_6 was shown to be one constituent of this black layer.

Oxygen difluoride has been observed as a byproduct in the production of perchloryl fluoride ClO_4F by reaction of elemental fluorine with 60% perchloric acid in a trickle column packed with glass chips [31]. It appears that the fluorine reacted with H_2O before it began to react with HClO_4 , concentrating the HClO_4 in the process.

Oxygen difluoride may be an unwanted byproduct of the fluorine production if the $\text{KF} \cdot 2\text{HF}$ electrolyte is not carefully dried to start with. The fluorine thus produced contains oxygen difluoride as a contaminant which needs to be separated to prevent clogging of liquid fluorine feed systems in rocket engines.

The economics of OF_2 production based on four processes described in the literature were reinvestigated [32]. These four processes were: **(1)** fluorine-caustic **(2)** fluorine-water catalyzed by alkali fluorides, **(3)** electrolysis of water in hydrogen fluoride, and **(4)** electrolysis of oxygen in hydrogen fluoride using a porous anode. Oxygen difluoride was produced at Air Products & Chemicals Inc. Allentown, PA, USA, without purification in 65–70% yield by the caustic-fluorine process at fluorine feed rates of 0.1 and 0.2 lb/h over a wide range of operating variables. Oxygen difluoride selling prices calculated for the caustic-fluorine method, the fluorine-water method, and the direct electrolytic method were estimated from \$55/lb at 4000 lb/year down to \$8/lb at approximately 60000 lb/year (as of 1970). From previous work it appeared that the fluorine-caustic process was the easiest to develop. Unless the process can operate continuously, the on-stream efficiency may be low because of operating problems in the fluorine section of the plant. Further scale-up was planned to gain more information on corrosion and heat effects on yield and on-stream efficiency with a 2 lb/h fluorine reactor. The economic comparison of the fluorine-caustic, fluorine-water, and direct electrolysis methods showed that the processes were rate and investment rather than process-dependent, and that the final price hinged on how the equipment was depreciated. It was concluded that at that time (1970) the fluorine-caustic offered the least expensive method for making OF_2 at rates at or below 10000 lb/year.

After OF_2 was no longer commercially available, for a short time NASA/JPL operated a pilot plant for production of OF_2 by reaction of fluorine with potassium hydroxide in water at 283 K (10 °C) [33]. Excess OF_2 and F_2 was dissipated by combustion of charcoal in a burn barrel. Byproduct potassium fluoride was reacted with calcium hydroxide to form insoluble, non-toxic calcium fluoride and to regenerate potassium hydroxide. The pilot plant was located at the JPL Edwards Air Force Base facility [34]. They achieved a yield of 78% of a high purity OF_2 product.

As of 2014, research quantities of OF_2 were available from at least one supplier, BOC Sciences, but it is no longer listed as of 2021 [35].

2.3 Physical Properties of Oxygen Difluoride

A good starting point for a summary of physical properties of oxygen difluoride was the product information bulletin once provided by Allied Chemical to its customers and prospective customers, but it is no longer available [36]. For additional information see also [4, 9, 10].

2.3.1 Boiling and Freezing Point of Oxygen Difluoride

Physical properties of oxygen difluoride are summarized in Table 2.

Table 2: Physical properties of oxygen difluoride.

Property	SI units	MKS units	Source	Year	References
Molecular mass	53.9962 g/mol	18.5198 mol/kg	NIST	1959	[37]
Freezing/melting point	49.35 K	−223.8 °C	Chemistry		
Freezing/melting point	49.4 K	−223.7 °C	WebBook		
Boiling point	127.85 K	−145.3 °C	Schnizlein et al.	1952	[38]
Boiling point	127.9 K	−145.2 °C	NIST Chem WebBook	1959	[37]

2.3.2 Density of Oxygen Difluoride

Data for the density of liquid oxygen difluoride are listed in Table 3. The density of liquid oxygen difluoride at 83 K = −190 °C is 1.65 g/cm³.

2.3.3 Vapor Pressure of Oxygen Difluoride

Vapor pressure data from two different sources are compared in Figure 1. The vapor pressure data in Table 4 have been curve-fitted and can be expressed by the equation:

$$\log p_v = 7.2242 - 555.42/T$$

where p_v is the vapor pressure in mmHg and T in the temperature in kelvin. A different Antoine equation applicable for the temperature range 77.0–128.5 K can be downloaded from the NIST Chem WebBook:

$$\log (P)_{10} = 5.26568 - (758.401/(T + 15.742))$$

where P is the vapor pressure in bar and T is the temperature in kelvin. The vapor pressure equation from NIST Chem WebBook (solid black line in Figure 1) gives notably lower vapor pressures than the equation from Schnizlein et al. (dashed line). Vapor pressure data for oxygen difluoride are summarized in Table 4.

Table 3: Density of liquid oxygen difluoride.

Data source: [38]

^a Calculated from the curve-fitted equation $\log p_v = 7.2242 - 555.42/T$; p in mmHg; T in K

Vapor pressure data from a Thiokol RMD report [40] illustrated in Figure 2 cover a wider range than the Schnizlein data.

2.3.4 Viscosity of Liquid Oxygen Difluoride

Viscosity data for saturated liquid OF₂ are available only over a narrow temperature range from 120 to 127 K, just below the normal boiling point. The dynamic (=absolute) viscosity in this range can be expressed by the equation

$$\log \eta = 131.5/T - 1.5768$$

where η is the viscosity in cPs and T is the temperature in kelvin. The viscosity derived from this equation is listed in the last column of Table 5.

Figure 2: Vapor pressure of liquid OF_2 as a function of temperature (reproduced and modified from [9])

A different equation for the viscosity of liquid OF_2 was extrapolated over a wider temperature range:

$$\log \eta = 112.4/T - 1.4508$$

where η is the viscosity in cPs and T is the temperature in kelvin. Viscosity data are graphed in Figure 3 and listed in Table 6.

The critical point property data of oxygen difluoride are listed in Table 7.

2.3.5 Miscibility of Liquid Oxygen Difluoride with Other Oxidizers

Because liquid oxygen difluoride is not hypergolic with most fuels at the temperature of its normal boiling point, more energetic fluorine oxidizers have been sought to make it hypergolic.

Table 5: Dynamic viscosity of liquid oxygen difluoride.

Temperature		Density	Viscosity, measured	Viscosity, calculated ^a
°C	K	g/cm ³	cPs	cPs
-145.8	127.3	1.523	0.2852	0.2859

Data source: [39]

^a Calculated from $\log \eta = 131.5/T - 1.5768$; η in cPs; T in K

For its potential use as an oxidizer in rocket propellants, it is important to know if and to what extent OF₂ is miscible with other liquid oxidizers, in particular those containing oxygen. A wide range of oxidizers (NOF, NO₂F, NF₃, N₂F₄, ClO₃F, ClF₃) were tested for miscibility and potential inadvertent interactions with OF₂ [41, 42]. The binary systems NF₃/OF₂, ClO₃F/OF₂, and N₂F₄/OF₂ exhibited complete miscibility over the entire range of mixture ratios, as did a ternary mixture of ClF₃/ClO₃F/OF₂ (under pressure at 195 K = -78 °C).

Liquid OF₂ was miscible in a molar ratio of 1:1 with liquid CF₄ at 90 K, CClF₃ at 90 K, CH₄ at 90 K, N₂F₄ at 110 K, and Kr at 120 K [43]. Liquid oxygen difluoride mixes homogeneously in all proportions with liquid F₂ at 77 K, with LOX and liquid ozone (LOZ) at 90 K, with liquid O₃F₂ at 116 K, and with liquid ClF at 125 K. It also mixes homogeneously with liquid CH₄ at 90 K, but this mixture is very **dangerous**. It may detonate upon the slightest stimulus or temperature rise.

Chlorine monofluoride theoretically would be expected to be miscible with OF₂ because of the similarities in molecular weight, boiling points and the lack of intermolecular forces between the similar molecules. This has, in fact, been experimentally verified; however, when attempts were made to increase the fluorine content of the additive, for example, with ClF₃ instead of ClF, theoretical analysis of the system indicated that ClF₃ and OF₂ would not be expected to exhibit much solubility or miscibility because of the dissimilarity in their molecular weights and their boiling points (boiling point of OF₂ is 128 K = -145 °C and the boiling point of ClF₃ is 284 K = +11 °C). Experi-

mentally, there was no apparent solubility of ClF_3 in liquid OF_2 . Because of the even greater differences in molecular weight between ClF_5 and OF_2 , it was at first expected that OF_2 and ClF_5 would be miscible; however, contrary to the theoretical prediction, it was discovered that ClF_5 has some solubility in OF_2 even at liquid OF_2 temperatures and furthermore that it is possible to form completely miscible systems of OF_2 and ClF_5 at intermediate temperatures [44]. To investigate solubility of ClF_5 in OF_2 at liquid OF_2 temperatures, ClF_5 was condensed in a glass tube and then frozen therein. OF_2 was then condensed onto the solid ClF_5 in amounts of approximately 84% by volume OF_2 , 16% ClF_5 . The mixture was agitated and gradually warmed. The interface between the ClF_5 and OF_2 was observed to recede, indicating that there was some solubility of ClF_5 in OF_2 even at temperatures of about 128 K (-145°C). Although ClF_5 is slightly soluble in OF_2 at liquid OF_2 temperatures of approximately 128 K (-145°C), the system at that temperature does not appear to be completely miscible. It was found that at temperatures above 194.6 K (-78.5°C), the systems will be completely miscible up to the critical temperature of the system. The vapor pressure of OF_2/ClF_5 mixtures at 194.6 K (-78.5°C) was measured as a function of mixture ratio and showed a slight positive deviation from ideal behavior. A vapor pressure chart was included in the patent specification.

Oxygen difluoride is a good solvent for liquid ozone. Ozone solvents have been sought that would attenuate the detonability of pure liquid ozone without detracting too much from its performance as a rocket oxidizer. These solvents should not have a solubility gap such as the one found with LOX. Fluorocarbons were tried first, but they are inert diluents which detract from performance. Oxygen difluoride has the advantage that it is not only a good solvent for liquid ozone, but also a powerful oxidizer in its own right. Oxygen difluoride/ozone systems have been investigated and it appeared that ozone and oxygen difluoride are completely miscible over the entire range of mixture ratios and temperatures.

The ozone-oxygen difluoride system has shown promise as a rocket oxidizer [45]. The viscosities, densities, and surface tensions of binary mixtures showed no deviations from expected linear interpolation values. The vapor pressure indicated, as was the case with fluorine, that the ozone-oxygen difluoride system is completely homogeneous. No sensitivity measurements have been made, but no unusual hazards were

noted. Therefore, it appeared, at the very least, that ozone could be used to upgrade the performance of either fluorine or oxygen difluoride.

Stabilized liquid ozone was burned with gaseous hydrogen in a rocket engine [46]. Stabilization was accomplished by dissolving liquid ozone in liquid OF_2 . In two experiments, the O_3 concentration was 40 mass-% and when burned with GH_2 , resulted in an explosion in one case and calm burning in another; however, an explosion also occurred in one experiment with 10% O_3 and 90% OF_2 and very irregular combustion chamber pressures were encountered in several other experiments.

2.3.6 Solubility of Liquid Oxygen Difluoride in Inert Solvents

Solubility of OF_2 in water at $273\text{ K} = 0^\circ\text{C}$ and 11 atm is $6.8\text{ cm}^3\text{ OF}_2/100\text{ cm}^3\text{ H}_2\text{O}$. At atmospheric pressure it is $4.3\text{ cm}^3\text{ OF}_2/100\text{ cm}^3\text{ H}_2\text{O}$. Gaseous OF_2 is slightly soluble in water, and the solution obeys Henry's law with an absorption coefficient (liters of gas in 1 L of water) of 0.04297 at $293\text{ K} = 20^\circ\text{C}$ and 0.068 at $273 = 0^\circ\text{C}$. The solutions are not stable because a slow hydrolysis reaction takes place at room temperature:

Solutions of oxygen difluoride in partially or perfluorinated organic solvents, such as 1-fluoropropane or monofluoromethane have been patented as monopropellants [47].

2.3.7 Thermal Conductivity of Oxygen Difluoride

The thermal conductivity of liquid OF_2 is $0.26\text{ W m}^{-1}\text{ K}^{-1}$ at 90 K ($0.00061\text{ cal cm}^{-1}\text{ s}^{-1}\text{ K}^{-1}$ at -183°C , from reference [48]).

2.3.8 Thermodynamic Properties of Liquid and Gaseous Oxygen Difluoride

There is a wide scatter in the enthalpy of formation data reported for oxygen difluoride, in particular the liquid (Table 8). It seems that the experts cannot even agree on if the enthalpy of formation is positive or negative. Numbers range all over the ballpark. The best summary of thermodynamic data for gaseous OF_2 compiled by NIST contains a table listing 28 different numbers for the enthalpy of formation, ranging all the way from $+10.6$ to $+76\text{ kJ/mol}$, collected over a time span from 1930 to 1990 and originating from both experimental measurements and quantum mechanical computational chemistry predictions.

Based on the three fundamentals of $\gamma_1 = 833\text{ cm}^{-1}$, $\gamma_2 = 492\text{ cm}^{-1}$, and $\gamma_3 = 1110\text{ cm}^{-1}$, the thermodynamic functions of OF_2 gas between 298 and 1500 K were calculated [53]. The numbers for 298 K were $-(F_0 - H_0)/T = 210.6\text{ J mol}^{-1}\text{ K}^{-1} = 50.31\text{ cal mol}^{-1}\text{ }^\circ\text{C}^{-1}$, $S_0 = 246.7\text{ J mol}^{-1}\text{ K}^{-1} = 58.93\text{ cal mol}^{-1}\text{ }^\circ\text{C}^{-1}$, and $C_p = 42.2\text{ J mol}^{-1}\text{ K}^{-1} = 10.08\text{ cal mol}^{-1}\text{ }^\circ\text{C}^{-1}$. Their tentative proposed enthalpy of formation $(\Delta H_f)_{298}$ was $+23.0\text{ kJ/mol} = +5.5\text{ kcal/mol}$.

Table 8: Thermodynamic properties of liquid and gaseous oxygen difluoride.

	SI units	MKS units	Source	Year	References
Molar heat capacity, C_p , gaseous at 298 K	43.32 J mol ⁻¹ K ⁻¹	10.349 cal mol ⁻¹ °C ⁻¹	JANAF	1969	[49]

Enthalpy of formation (ΔH) ₂₉₈ liquid	-35.6 kJ/mol	-8.5 kcal/mol			
Entropy S°_{gas} , 1 bar	247.46 J mol ⁻¹ K ⁻¹	59.14 cal mol ⁻¹ °C ⁻¹	NIST Chem Web-Book, Chase	1998	[37]
Heat of evaporation (ΔH) _{evap.}	11.2 kJ/mol at 123.8 K 11.08 kJ/mol at 127.8 K	2.680 kcal/mol at -144.8 °C 2.650 kcal/mol at -145.3 °C	Allied Chemical Streng	1959 1963	[36] [4]
Entropy of evaporation (ΔS) _{evap.}	86.4 J mol ⁻¹ K ⁻¹	20.65 cal mol ⁻¹ °C ⁻¹	Allied Chemical	1959	[36]

The widely cited number (+7.6 ± 2 kcal/mol) listed in Evans, Munson, and Wagman [51], which was an average of three numbers reported by earlier investigators, is generally considered unreliable and should be ignored.

The most accurate enthalpy of formation of OF₂ was obtained from constant pressure flame calorimetry measurements at NIST (former NBS) by burning OF₂ with H₂ and absorbing the formed HF and H₂O [52]. The enthalpy of formation of OF₂ was measured in a calorimeter by allowing OF₂ to react with H₂ in a closed bomb with a bottom layer of water to absorb the HF formed in the reaction:

The standard enthalpy of formation of gaseous OF₂ calculated from the known heats of formation of the products was -18.4 ± 3.4 kJ/mol (-4.40 ± 0.82 kcal/mol) [50, 54], but this number is totally out of line with all the other measurements and there must have been an instrumental or computational error leading to the negative number.

The gas phase heat capacity of OF_2 can be calculated by a Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$, τ is the temperature in kelvin divided by 1000: $\tau = \text{K}/1000$, and A, B, C, D, and E are constants listed in Table 9 for two temperature ranges.

Table 9: Coefficients for thermodynamic property Shomate equations for oxygen difluoride.

Temperature range, K	298–600	600–6000

H	24.51803	24.51803

Data source: [37, 49]; data last reviewed in September 1995

According to the *NIST Chemistry WebBook* web site, the standard enthalpy of formation of the OF_2 gas is $\Delta H_f^{298} \text{ gas} = +24.52 \pm 1.59 \text{ kJ/mol}$. The differential enthalpy of formation of gaseous oxygen difluoride as a function of temperature can be expressed by the equation

$$H^\circ - H_{298.15}^\circ = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - H$$

where H° is the standard enthalpy in J mol^{-1} , τ is the temperature in kelvin divided by 1000: $\tau = \text{K}/1000$, and A, B, C, D, E, F, and H are constants listed in Table 9 for two temperature ranges. The standard entropy of gaseous oxygen difluoride as a function of temperature can be expressed by the equation

$$S^\circ = A \times \ln(\tau) + B\tau + \frac{C\tau^2}{2} + \frac{D\tau^3}{3} - \frac{E}{2\tau^2} + G$$

where S° is the standard entropy in $\text{J mol}^{-1} \text{K}^{-1}$, τ is the temperature in kelvin divided by 1000: $\tau = \text{K}/1000$, and A, B, C, D, E, and G are constants listed in Table 9 for two temperature ranges.

The thermochemical properties of all oxygen fluorides and their associated free radicals have been summarized and the JANAF thermochemical tables for oxygen fluorides going all the way up to O_8F_2 have been updated by NIST, but sufficient infor-

mation was not available to generate thermochemical tables for any condensed phase species [12]. Table 10 gives a summary of recommended thermochemical data for gas phase oxygen fluorides including some free radicals. The [] brackets indicate estimated values.

Table 10: Thermodynamic properties of the gaseous oxygen fluorides.

Temperature, K	0	298.15	298.15	298.15	298.15
Compound	ΔH_0 kJ/mol	ΔH_f kJ/mol	ΔG_f° kJ/mol	C_p° J mol ⁻¹ K ⁻¹	S_0 J mol ⁻¹ K ⁻¹

Data source: [12]

The NIST-JANAF thermochemical table values for the thermochemical properties of oxygen fluorides issued in 1996 were critically examined on the basis of high-level density functional and *ab initio* G2 calculations [55]. Special attention was given to the enthalpies of formation and it was concluded that, although the proposed values for OF(G), FOO(G) and FOF(G) were reasonable and in agreement with previously recommended values, the enthalpy of formation recommended for FOOF was too low. Instead, a value about 50% larger was proposed and it was recommended that the original 1959 experimental determination of this enthalpy of formation should be repeated.

The theoretical enthalpy of formation ΔH_f (298 K) value obtained for gaseous FOF (¹A₁) was +24.68 ± 1.25 kJ/mol (+5.9 ± 0.3 kcal/mol), and for FOOF (¹A) it was +26.78 ± 2.93 kJ/mol = +6.4 ± 0.7 kcal/mol [56]. The value for FOF is different from experimental results which gave +19.20 ± 2.09 kJ/mol = +4.59 ± 0.5 kcal/mol. See also reference [57].

A narrow range of values (155–197 kJ/mol = 37–47 kcal/mol) for the O–F bond energy was obtained from the heat of formation and normal assumptions for the other bonds present in molecules with O–F bonds for the species for which data were available [58]. The average value for the energy of the O–F bond for all O–F bonded species was found to be 180 kJ/mol (43 kcal/mol), which corresponds very closely to the value of 188 kJ/mol (45 kcal/mol) derived from the heat of formation of oxygen difluoride. The variation found in the O–F bond energies for the species is less than that observed for other bonds, depending on the nature of the compound they are attached to.

2.3.9 Molecular Structure of Oxygen Difluoride

The energy release that drives a rocket is founded in the energy of chemical bonds being broken and made. In order to select the best rocket propellant from the group of oxygen fluorides, the energy of the O—F bond must be known. An excellent summary of bond lengths, bond angles and force constants in several of the O—F molecules was provided in [12].

The predicted heats of formation at 298.15 K and structures of 5 small oxygen fluoride molecules have been calculated by computational chemistry [56]. Good agreement with experiment was found for several structures.

In studying the molecular structure of OF₂ (is it similar to that of OH₂?), it was useful to have microwave spectra [59]. The values for the rotational constants together with the effective moments of inertia calculated from them were derived from 13 rotational absorption lines of which 9 of the lines could be assigned to rotational transitions of OF₂. It is highly unlikely that OF₂ would have the structure of a fluorosyl fluoride F—F=O but CAS has assigned this structure a CAS Registry number [86825-57-2], nevertheless.

The interatomic distance between the central oxygen atom and the two equivalent fluorine atoms and the angle formed between them were measured by several investigators, but the results vary, as summarized in Table 11.

Table 11: Molecular constants of the oxygen difluoride molecule.

Property	Result	Author	Year	References
O—F distance	1.3896 Å	Hilton et al.	1961	[59]
O—F distance	1.409 Å	Pierce, Jackson, and di Cianni	1961	[60, 61]
O—F distance	1.412 Å	JANAF	1969	
F—O—F bond angle	$2\theta = 104.163^\circ$	Hilton et al.	1961	[59]
F—O—F bond angle	$103^\circ 18'$	Pierce, Jackson, and di Cianni	1961a, 1961b	[60, 61]
Dipole moment	0.297 ± 0.005 D	Pierce, Jackson, and di Cianni	1961a, 1961b	[60, 61]

The publication by Chase [12] contains an excellent summary of bond lengths, bond angles, and force constants in the OF₂ molecule covering the time period from 1935 to 1994 with about 30 different sources of experimental measurements or theoretical calculations for the O—F bond length, many more than shown in above table [12].

A total of 17 rotational transitions of F₂O were measured in the region 13–60 GHz with Stark module spectrometers [60, 61]. Rotational constants, moments of inertia, the inertial defect and structural parameters of F₂O were derived from these measurements. A dipole moment of 0.297 ± 0.005 D was obtained.

Four valence force constants have been evaluated on the basis of Wilson's group theoretical method for OF₂ [62]. The observed fundamental frequencies were then utilized for the calculation of molar thermodynamic functions assuming a rigid rotator,

harmonic oscillator approximation for the temperature range from 100 to 1700 K. The O—F bond energy is 58 kcal/bond = 2.52 eV.

Self-consistent field and large-scale configuration interaction studies with double zeta and extended basis sets were performed on F₂O for its geometry, vertical electronic excitation energies, and vertical ionization potentials [63]. Large-scale configuration interaction methods gave the best agreement with the experimentally measured distance (1.41 Å).

Ab initio predictions at the self-consistent field (SCF), double excitation configuration interaction (CISD) and double excitation coupled cluster (CCSD) levels were reported for OF₂ using the double zeta plus polarization (DZP) and triple-zeta plus polarization (TZP) basis sets [64]. The calculated geometries, rotational constants, dipole moments, fundamental frequencies, isotopic frequency shifts, vibration-rotation interaction constants, centrifugal distortion constants, Coriolis coupling constants and IR band intensities were compared with experimental data. The best agreement was usually found for the CCSD results. The experimentally derived cubic force field of OF₂ was reproduced well so that the predicted quartic force field of OF₂ was also expected to be realistic.

2.3.10 Dipole Moment of Oxygen Difluoride

The dipole moment of OF₂ has been determined from the Stark effect on two rotational frequencies [65]. The dipole moment of 0.1759 ± 0.0010 debye was about 2.1% of that calculated for a simple ionic model. The dielectric constant, polarization and dipole moment of OF₂ were compared to those of SF₄ [66]. A condenser was mounted in a cylindrical glass vessel which was immersed in the thermostat bath. Capacities were measured with the OF₂ gas at atmospheric pressure over the temperature ranges 195–353 K (–78° to +80 °C). The dipole moment of OF₂ gas was 0.4 ± 0.1 D for a polarization of 5 cm³/mol. The value for OF₂ is much smaller than that for OH₂. The dipole moment of OF₂ was reported as 0.297 ± 0.005 D [60, 61].

2.3.11 Optical Properties of Oxygen Difluoride

2.3.11.1 UV/Visible Spectra of Oxygen Difluoride

In the visible/UV spectrum between 8000 and 2100 Å, absorption of light starts at about 5400 cm^{–1}, is purely continuous and shows maxima at 4210 Å = 23800 cm^{–1}, 3580 Å = 28000 cm^{–1}, and 2940 Å = 34000 cm^{–1}. A very abrupt ascent of absorption is observed at about 2640 Å = 38000 cm^{–1}, but the maximum of absorption is not yet reached at 2130 Å = 47000 cm^{–1}.

The photoabsorption and dissociation processes of Cl₂O₂ and Cl₂O have attracted considerable attention since these processes are involved in the ozone depletion in the Antarctic stratosphere. By analogy, the photoabsorption and dissociation processes of O₂F₂ and OF₂ are of interest. The excitation spectrum of OF₂ up to about 13.0 eV was calculated and compared to theoretical results. The shape and main features of

the calculated OF_2 spectrum was found to be very similar to that of Cl_2O , each state being blue-shifted by 2–3 eV, and the valence and Rydberg excited states were clearly discriminated [67].

2.3.11.2 Infrared Spectra of Oxygen Difluoride

The infrared spectrum of OF_2 has been re-examined from 2–25 μm with a prism spectrometer and selected regions further examined with a grating spectrometer [68]. Several bands observed by previous investigators were shown to be caused by impurities. An assignment of fundamental modes could be made which was consistent with dimensions of the molecule obtained from electron diffraction data. Two new bands were observed and assigned to combinations of the fundamentals. The observed frequencies and their assignments were: $\nu_1 = 928 \text{ cm}^{-1}$, $\nu_2 = 461 \text{ cm}^{-1}$, $\nu_3 = 831 \text{ cm}^{-1}$, $\nu_1 + \nu_3$, and $2\nu_2 + \nu_3$ at 1731 cm^{-1} , $3\nu_3 = 2460 \text{ cm}^{-1}$, $2\nu_1 + \nu_3 = 2643 \text{ cm}^{-1}$.

The absorption spectrum of OF_2 dissolved in liquid N_2 at 80 K was obtained and the frequency and intensity of the absorption bands were determined [69].

The IR spectra of highly purified OF_2 were measured in standard 10-cm gas cells equipped with silver chloride windows at pressures up to one atmosphere in the region from 350 to 4000 cm^{-1} [70]. Figure 4 is a composite of three IR spectra of gaseous OF_2 taken at different partial pressures and path lengths. The sharp drop-off at the low frequency side is due to absorption by the AgCl windows on the cell. Note that the wavenumber scale is not continuous but composed of four sections showing different parts of the spectrum.

Figure 4: Composite of three IR spectra of OF_2 taken at different partial pressures and path lengths (reprinted and modified from [70], with permission from © 1966 Elsevier; permission conveyed through RightsLink.)

The study of gaseous OF_2 IR spectra indicated that a simple harmonic oscillator model is inadequate to describe the vibrational spectrum and that Fermi resonances must be taken into consideration. Several transitions fall within a 100-cm^{-1} range of each other introducing the possibility of widespread resonance effects in the molecule. These effects are evident in the complicated spectra patterns exhibited in the overtones and combinations observed.

Portions of the ν_3 asymmetrical stretch band of OF_2 were measured under conditions of Doppler-limited resolution and the frequencies of 176 transitions were measured with a nominal accuracy of 0.001 cm^{-1} , see reference [71]. The remaining band constants were determined by constraining the ground state parameters to the values determined earlier and carrying out a simultaneous fit of the existing IR and $\nu_3 = 1$ microwave data. No evidence for the anticipated effects of weak Coriolis coupling for levels with $K - 1 = 16$ and $J = 30$ was observed although such effects may be present in levels with much higher quantum numbers.

2.3.11.3 Raman Spectra of Oxygen Difluoride

The Raman spectra of liquid OF_2 were obtained and compared to IR spectra [72]. Polarization studies confirmed earlier infrared band assignments and supported the existence of Fermi resonance between ν_1 and $2\nu_2$.

The Raman spectra of solid OF_2 proved to be difficult to obtain because of the colored nature of this compound. The liquid is yellowish brown whereas the solid still retains a light brown coloration. A comparison of Raman and IR of crystalline OF_2 indicated that this solid is not centro-symmetric and contains at least two molecules per primitive cell, on sites of symmetry C_s or C_1 [73]. Absorption bands at 461, 821, and 925 cm^{-1} were found in gas IR, liquid Raman, and solid Raman and solid IR spectra. The most striking feature in the IR spectrum of crystalline OF_2 was the broad band on the high-frequency side of the 812 cm^{-1} peak. In the Raman spectrum, a sharp peak was observed at 845 cm^{-1} , its frequency being approximately coincident with the limit of the IR reflection band. The far-IR spectrum of crystalline OF_2 showed seven bands in the $40\text{--}90\text{ cm}^{-1}$ region, all of these having Raman-active counterparts with almost identical frequencies.

The argon matrix Raman spectra of $^{16}\text{OF}_2$ and $^{18}\text{OF}_2$ at 16 K had frequencies within one wave number of analogous IR spectra [74]. In addition, laser photo-detachment of fluorine atoms has provided significant yields of the $\bullet\text{OF}$ and $\bullet^{18}\text{OF}$ free radicals. Temperature cycling and depolarization ratio measurements aided in identifying new chemical species and making vibrational assignments.

2.3.12 Microwave Spectra of Oxygen Difluoride

The molecular structure of OF_2 has been studied by microwave spectroscopy based on 13 rotational absorption lines [75]. The frequencies of the lines were measured with a precise frequency standard. Nine of the lines were assigned to rotational transitions

of OF_2 using a graphical method. The values for the rotational constants together with the effective moments of inertia calculated from them were $A = 61567.71 \text{ MHz}$, $I_A = 8.21096 \text{ amu, \AA}^2$; $B = 11066.54 \text{ MHz}$, $I_B = 45.6809$; $C = 9343.85 \text{ MHz}$; $I_C = 54.1088 \text{ amu, \AA}^2$. The effective values for the O—F interatomic distance and the apex angle 2θ calculated from I_A and I_B were $r = 1.3896 \text{ \AA}$, $2\theta = 104.163^\circ$.

Microwave absorption spectra of the OF_2 molecule in the vibrationally excited states with $\nu_1 = 1$, $\nu_2 = 1$ and 2, and $\nu_3 = 1$ were measured and analyzed with consideration for the Fermi resonance between ν_1 and $2\nu_2$ vibrational levels [76]. The degree of mixing between the two states and quadratic force field were determined from the inertia defects. Cubic potential constants and equilibrium structures were obtained from the vibration-rotation interaction constants.

Radio frequency transitions within six different rotational levels of oxygen difluoride have been observed in the presence of external electric fields [77]. These data were analyzed in terms of the dipole moment, polarizability anisotropies, spin rotation and spin-spin interactions: $\mu = 0.30818(3) \text{ D}$, $aaa-abb = 1.389(8) \text{ \AA}^3$, $aaa-acc = 1.883(10) \text{ \AA}^3$, $Maa = 59.60(7) \text{ kHz}$, $Mbb = 25.05(11) \text{ kHz}$, $Mcc = 51.39(8) \text{ kHz}$, and $1/R^3 = 0.0941(5) \text{ \AA}^{-3}$.

A very detailed analysis of the rotational and centrifugal distortion constants of OF_2 has been posted on a NIST web site as part of their triatomic species spectral data file [78]. Historically, the analysis of the rotational and centrifugal distortion constants for OF_2 had caused considerable difficulty. The first spectra on OF_2 had been incorrectly interpreted and later Pierce, di Cianni, and Jackson [79] provided the correct assignments from a detailed centrifugal distortion analysis of new spectral measurements.

2.3.13 Photoelectron Spectra of Oxygen Difluoride

Additional information on bonding states and ionization energies in OF_2 can be obtained from photoelectron spectra. The photoelectron spectrum of OF_2 pertaining to ionizations to the ground and low-lying excited electronic states of F_2O^+ was investigated theoretically [80]. The near equilibrium potential energy surfaces of the ground electronic state of OF_2 and the mentioned ground and excited electronic states of F_2O^+ reported by others for the C_{2v} configuration are extended for the C_s geometry assuming a harmonic vibration along the asymmetric stretching mode [81].

2.3.14 Electrical Properties of Oxygen Difluoride

Liquid oxygen difluoride does not autodissociate like BrF_3 and the electrical conductivity is not measurable. Oxygen difluoride in the dark does not have an electronic spin resonance (ESR) signal and is not paramagnetic [82, 83]. When illuminated with UV at $3660 \text{ \AA}$, an ESR signal (a strong doublet with a hyperfine splitting of 13.5 Gauss) of a free radical was observed, but it was not positively identified. Most likely it was $\cdot\text{OF}$ free radical and not a multi-oxygen fluoride. The intensity of the ESR signal increased

with continued illumination, reached a maximum and then decayed. The rate of photolysis was temperature dependent.

The electrical conductivity of liquid OF_2 is $\leq 1.4 \times 10^{-10} \Omega^{-1} \text{cm}^{-1}$ and $\leq 5.16 \times 10^{-10} \Omega^{-1} \text{cm}^{-1}$ at 77 and 113 K (−196 and −160 °C), respectively [84]. Only few chemicals that dissolve in OF_2 will cause an increase in conductivity.

2.3.15 Magnetic Properties of Oxygen Difluoride

2.3.15.1 Nuclear Magnetic Resonance Spectra of Oxygen Difluoride

Direct comparisons between ^{19}F nuclear magnetic resonance (NMR) spectra of liquid and gaseous F_2 , OF_2 , and NF_3 had not been reported prior to 1966 [85]. The chemical shifts of liquid and gaseous F_2 , OF_2 , and NF_3 are listed in Table 12.

Table 12: ^{19}F NMR shifts in liquid and gaseous F_2 , OF_2 , and NF_3 .

	^{19}F NMR shifts ^a		
	F_2 (ppm)	OF_2 (ppm)	NF_3 (ppm)
Liquid at 77 K	-422 ± 1	-249 ± 1	-142 ± 1
Gas	-419 ± 1	-248 ± 1	-138 ± 1
Difference gas–liquid	3	1	4

^a In relation to CFCl_3 reference.

Data source: [85]

As can be seen in Table 12, the chemical shifts for liquid F_2 , OF_2 , and NF_3 were all lower than the corresponding shifts in the gas. This downfield shift due to liquefaction is similar to that observed in the proton magnetic resonance studies of the first row hydrides.

The ^{19}F NMR spectra of liquid F_2 , OF_2 , O_2F_2 , and O_3F_2 were measured and compared [86]. The shifts of O_2F_2 and O_3F_2 were the furthest downfield of any simple fluorine compound yet reported. In order to completely understand the NMR shifts, they have to be measured at several temperatures. The vast difference in chemical shift of O_2F_2 and O_3F_2 indicated that the fluorine nuclei (hence fluorine-oxygen bonding) are considerably different in O_2F_2 and O_3F_2 as compared to OF_2 . The structures of F_2 , OF_2 , and O_2F_2 can be well characterized, and hence their ^{19}F NMR signals can be interpreted in accordance with their structures. The “one-electron” bond model in O_2F_2 would result in a ^{19}F nucleus, which has a very low shielding constant and is thus consistent with the ^{19}F NMR spectrum. A summary of chemical shifts is presented in Table 13. The O_3F_2 is given in quotation marks, since there is some uncertainty about the reality of the compound. A model for O_3F_2 is postulated in which this species is made up of O_2F_2 and “interstitial” O_2 .

Table 13: ^{19}F NMR shifts for liquid F_2 , OF_2 , O_2F_2 , and O_3F_2 .

Compound	Temperature, K	Shift, ppm ^a
F_2	77	-422 ± 1
OF_2	77	-249 ± 1
O_2F_2	145	-865 ± 1
" O_3F_2 "	<145	-877 ± 5

^a In relation to CFCl_3 reference.

Data source: [86]

Indirect spin-spin coupling tensors, $\mathbf{J}$, are of importance in interpreting NMR spectra. For example, a great deal of experimental and theoretical work has focused on the characterization of $\mathbf{J}$ couplings observed across hydrogen bonds. Similar couplings may occur between fluorine bonds and contribute to the association of molecules. Symmetry properties of indirect nuclear spin-spin coupling tensors can be calculated by a first principles method and results for OF_2 were shown [87]. Measured $\mathbf{J}_{\text{iso}}(^{19}\text{F}, ^{17}\text{O})$ in OF_2 is $\pm 300 \pm 30$ Hz and the predicted number was very close. See also reference [88].

2.4 Chemical Properties of Oxygen Difluoride

Oxygen difluoride is a weaker oxidizer than elemental fluorine or halogen fluorides. It will eventually react with most organic substances, but only at higher temperatures than fluorine or halogen fluorides. In contradistinction to fluorine it does not autoignite with methane, kerosene, charcoal or ammonia at room temperature. Once ignited, the combustion reaction is just as energetic as those supported by fluorine as an oxidizer. The reaction with diborane is hypergolic at room temperature and this makes a good rocket propellant combination [89].

2.4.1 Decomposition of Oxygen Difluoride

2.4.1.1 Thermal Decomposition of Oxygen Difluoride

Oxygen difluoride is thermally stable under normal storage conditions. Above 523 K (250 °C) it begins to decompose into its constituents. The activation energy of the homogeneous gas phase reaction is 172 kJ/mol (41 kcal/mol). Other sources reported the activation energy of thermal decomposition as 169.8 ± 12.5 kJ/mol (40.6 ± 3 kcal/mol). The reaction has been found to be about first-order with respect to OF_2 when a large excess of inert diluent gas is present, with the pseudo first-order constant proportional to total pressure and found to be approximately second-order when only pure OF_2 is used. The reported activation energies were in the range of 130–176 kJ/mol (31–42 kcal/mol).

Although the kinetics of the thermal decomposition of OF_2 have been studied extensively, there remained considerable doubt as to the exact mechanism of pyrolysis. This reaction has been investigated with static reactors, flow reactors, and shock tubes. This reaction would often precede the ignition of OF_2 with fuels at elevated temperature and therefore must be understood in developing OF_2 as a rocket propellant.

The thermal decomposition of oxygen difluoride has been investigated in aluminum static reactors at 563–634 K [90]. The reaction had an induction period followed by an apparent first-order decay in the pressure region of 10–5500 mm Hg. The decomposition of OF_2 is a complex process, possibly proceeding via a chain reaction. The observed first-order constant was

$$k_1 = 10^{9.0} \exp(-31000/RT) \text{ s}^{-1}$$

The thermal dissociation of Ar-diluted OF_2 behind incident shock waves was investigated in the temperature range 860–1300 K [91]. The course of the dissociation was followed by means of UV absorption spectroscopy utilizing a light beam centered at 220 nm. The dissociation exhibited two phases: a slow initiation phase followed by an accelerating rate. Initial slope measurements gave a second-order rate constant of

$$k = 10^{14.2} \exp(31500/RT) \text{ mL mol}^{-1} \text{ s}^{-1}$$

The results were interpreted as being indicative of a chain mechanism.

The thermal decomposition of OF_2 was studied in a single-pulse shock tube over the temperature range 770–1390 K [92]. For temperatures below 1000 K these results were in excellent agreement with the previous shock tube data; however, all rates obtained by conventional techniques, either in static or in flow systems, proved to be higher than those derived from the shock tube techniques. This was attributed to surface effects which cannot be avoided in conventional systems. The following scheme was proposed:

with

$$k_1 = 10^{17.3 \pm 1.4} \exp(-42.5 \pm 4.1) \text{ mL mol}^{-1} \text{ s}^{-1}$$

and

$$k_2 = 10^{12.10 \pm 0.12} \text{ mL mol}^{-1} \text{ s}^{-1}$$

The reverse reactions cannot be neglected even in the early stages of reaction. The bond dissociation energy $D(\text{FO}-\text{F})$, was found to be $178.6 \pm 17.1 \text{ kJ/mol}$ ($42.7 \pm 4.1 \text{ kcal/mol}$). The mechanism of the OF_2 decomposition was also discussed.

It was already shown that oxygen inhibits OF_2 decomposition. Another free radical scavenger, CO was therefore also tested for its effect on OF_2 decomposition [93]. The

kinetics of the reaction between oxygen difluoride with carbon monoxide were studied in shock tubes between 800 and 1400 K. Some of the experiments were done with a single pulse tube. These provided data on the production of CO_2 , O_2 , and F_2CO . In addition, time-resolved optical measurements were made behind incident shock waves. The reaction between OF_2 and CO leads to the production of significant amounts of F_2CO , which results in a temperature increase that becomes more important at the lower temperatures. For shock tube OF_2 kinetic studies, see also reference [94].

Oxygen difluoride in helium gas carrier has been decomposed at temperatures from 773 to 973 K and at residence times from 1 to 10 ms using a tubular flow reactor coupled to a mass spectrometer [95]. The reactor was made from nickel and was 7.5 cm (3 in.) long and had a diameter of 6.1 mm (0.25 in.). The rate expression found for the bimolecular rate coefficient over the temperature range from 723 to 923 K was

$$\log k = 9.78 - \frac{7065}{T} \text{ L mol}^{-1} \text{ s}^{-1}$$

No evidence for the oxy fluoride ($\cdot\text{OF}$) radical was found. This thermal decomposition does not appear to be a simple unimolecular decomposition. Additional tests were planned to be done in a shock tube [96]. The activation energy of OF_2 decomposition in a flow reactor was 142 kJ/mol (34 kcal/mol) [237].

The rate and mechanism of pyrolysis of OF_2 has been studied over the temperature range of 603–704 K (330–431 °C) in a stirred-flow Monel reactor, and a concentration range of 1–10 mol % OF_2 in helium at a total pressure of 1 atmosphere [97]. The only observed products were oxygen and fluorine. The reaction was somewhat less than first order with respect to reactant concentration. The initial rate data could be represented by the following equation:

$$-[\text{d}(\text{OF}_2)/\text{d}t]_0 = k_2(M)(\text{OF}_2)_0 + k_{3/2}(M)(\text{OF}_2)^{1/2}$$

where k_2 and $k_{3/2}$ are the second-order and 3/2-order rate constants and M is the total concentration of species in the reactor. The Arrhenius plot of the k_2 values gave the following equation:

$$k_2 = 10^{16.9 \pm 0.6} \exp(39200 \pm 1700/RT)$$

where k_2 is the second-order rate constant in $\text{mL mol}^{-1} \text{ s}^{-1}$ and T is the temperature in kelvin.

The thermal decomposition of OF_2 has been investigated in reactors made of Mg, Al or quartz using a static method [98]. The temperature was varied between 501 and 583 K and the total pressure between 1.3 and 100 kPa (10 and 750 mm Hg). The reaction was homogeneous and at moderate and high pressures essentially of second order. In the absence of foreign gases the second-order constant increased slowly with decreasing pressure. All added gases increased the reaction rate.

2.4.2 Photolysis of Oxygen Difluoride

Because the decomposition of OF_2 can also be initiated by intense light, it should be stored only in the dark [99].

Oxygen difluoride is an effective fluorinating agent, but for many fluorinating reactions the reacting mixture has to be illuminated with UV to achieve the desired products at a reasonable rate of formation.

The photoionization efficiencies of the ions F_2O^+ and OF^+ have been measured in a photoionization mass spectrometric study of gaseous OF_2 [100]. The adiabatic first ionization potential of OF_2 was 13.11 ± 0.01 eV. The region near threshold (13.11 – 13.6 eV) had a structure that was interpreted as vibrational autoionization. Additional peaks at 13.81 , ~ 15 , and ~ 15.5 eV were interpreted as Rydberg levels that decay by an electronic autoionization mechanism and which converge to the second ionization potential at 16.17 eV. An upper limit for the appearance potential of OF^+ (0 K) was 14.438 eV, quite different from the electron impact value of 15.8 ± 0.2 eV. That implies $\Delta H^\circ_f(\text{OF}) = +109.2 \pm 9.6$ kJ/mol ($+26.1 \pm 2.3$ kcal/mol) and an ionization potential of $(\text{OF}) = 12.79 \pm 0.10$ eV.

2.4.3 Radiolysis of Oxygen Difluoride

A study of the radiolysis of liquid oxygen difluoride with γ -radiation from a ^{60}Co source was performed at a dose rate of 6.00×10^5 rad/h in stainless steel vessels and at a temperature of 77 K (-196°C) [101]. Samples were loaded into the vessels and pressure over the liquid was determined. Each vessel contained 5.0 g of OF_2 liquid, which filled about 20% of the available volume. When plotting the mols of gaseous decomposition products, O_2 and F_2 , as a function of radiation dose, it was noted that in this case the yield of decomposition products was not linear with dose as were other chemicals subjected to radiolysis. The fact that the yield was not constant but decreasing probably indicated a secondary reaction which was removing the gaseous products at a slow but definite rate. One such reaction which immediately suggests itself is the reverse reaction of O_2 and F_2 gas to reform OF_2 liquid. It is also possible that some O_2F_2 could be formed which would also condense at the temperature of these experiments and lead to an apparent decrease in the rate of decomposition of OF_2 . Since the rate of formation of decomposition products, and hence the G -value, decreased with increasing dose, the value at low doses is most important since that gives the maximum value and indicates the maximum rate of radiation-induced decomposition. The initial value was $G(\text{gas}) = 0.30$ molecules/100 eV. A G -value this low indicates liquid OF_2 is rather radiation resistant. The data further indicated a maximum gas build-up rate of about 6.9×10^3 mL/megarad. Assuming one and a half molecules of gaseous products for each molecule of liquid OF_2 decomposed, the G -value is $G(\text{OF}_2) = 0.20$ molecules/100 eV. This is equivalent to about $1 \times 10^{-3}\%$ decomposition per megarad.

2.4.4 Reactions of Oxygen Difluoride

Oxygen difluoride does not react with F_2 either in gaseous phase at temperatures up to 573 K (300 °C) or in liquid phase at cryogenic temperatures. No OF_3 or OF_4 was formed under these conditions. The O^{+2} just seems to be the highest state of oxidation we can oxidize oxygen to (for now). The mixtures of OF_2 with the other halogens, Cl_2 , Br_2 or I_2 , explode upon warming.

At elevated temperatures OF_2 reacts with glass forming SiF_4 and oxygen. With aqueous solutions of HCl, HBr, or HI oxygen difluoride reacts quantitatively, liberating free halogens:

The other three halogens are displaced also from their halide salts. Gaseous OF_2 does not ignite hypergolically when mixed with H_2 , CH_4 or CO , but the mixtures will explode when sparked. Oxygen difluoride reacts slowly with anhydrous NH_3 yielding NH_4F . A mixture of OF_2 with NO is slowly colored brown; NOF and NOF_2 are formed. A gaseous NO - OF_2 mixture may explode from a spark.

Pure NOF should not react with OF_2 . An explosion that was reported in the literature has later been blamed on NO contamination in the NOF that was used for the experiment.

Oxygen difluoride can be made to react with hot mercury to form mercury(II) fluoride and with platinum powder it will react at 473 K (200 °C) to form PtF_4 and O_2 .

The reaction of OF_2 with NO_2 leads to a mixture of NO_2F , NO_3F , and O_2 , and the proportions of products depend on the operating pressure. At low pressure, this is a useful method for preparation of NO_2F .

The thermal reaction between OF_2 and NO_2 was studied at 333–353 K (60–80 °C) [102]. The reaction took place with a pressure decrease, one mol of OF_2 being used up for each two mols of NO_2 . The reaction products varied with the total operating pressure and consisted of NO_2F , NO_3F , and O_2 . In the case of extremely high pressure, only the two fluorides and no O_2 are formed, the pressure change being 50% of the initial NO_2 content when using an excess of OF_2 . At very low pressure, only NO_2F and O_2 are formed in the mol ratio 4 : 1. The rate-determining step of the overall reaction is a bimolecular reaction:

with

$$k = 1.28 \times 10^8 e^{(-14475/RT)} \text{ L mol}^{-1} \text{ s}^{-1}$$

Liquid OF_2 does not react with liquid ozone. Liquid OF_2 has been tested as a non-reactive solvent for ozone.

The reaction of OF_2 with nitrosyl fluoride, FNO , resulted in a mixture containing FNO_2 , F_2 , NF_3 , and O_2 [103]. No ONF_3 was detected as a major product. Likely mechanisms to account for the formation of the observed products have been proposed on

the basis of high-level *ab initio* computations. According to those *ab initio* calculations, OF₂ should react in a bimolecular reaction with FNO forming either **(1)** FNO₂ and F₂ directly or **(2)** forming the peroxide species F₂N—O—O—F as an unstable intermediate, which then decomposes in a unimolecular reaction to yield NF₃ and O₂. Using quantum chemical calculations, the likely intermediate compound F₂N—O—O—F was shown to possess a true minimum on its potential energy surface and the structure and vibrational data of F₂N—O—O—F were calculated.

2.4.4.1 Hydrolysis of Oxygen Difluoride

The freshly synthesized OF₂ gas must be carefully dried prior to storage because it may slowly hydrolyze (corrosion by HF) or water (ice) crystals may cause clogging of orifices if liquid OF₂ is pumped into a rocket engine.

The basic hydrolysis of oxygen difluoride has previously been studied [104], but under such conditions that the rate-controlling step was the rate of dissolving of the gas in the water rather than the rate of hydrolysis when in solution. The hydrolysis of OF₂ follows the reaction

Oxygen difluoride does not behave as the anhydride of an acid. It has only a low solubility in water or even in cold 40% KOH. The progress of the hydrolysis of dissolved OF₂ in water was monitored with an ion-selective fluoride electrode and a pH electrode (which being a glass electrode, could only be used for pH up to 11) [105]. Runs were made with buffered solutions at preselected pH or with NaOH solutions. The presence of ions other than OH[−] in the buffered solutions had little or no influence upon the rate of hydrolysis of OF₂. At constant pH and temperature the rate was directly proportional to the concentration of OF₂. The rate equation may be written as

$$d[\text{OF}_2]/dt = -k[\text{OF}_2][\text{OH}^-]^{1/3} - 0.0105$$

where *k* is time was measured in seconds. The straight line in a graph (not shown) corresponded to *k* having a numerical value at 293 K (20 °C) of 4.1×10^{-3} where time is in seconds and concentrations are in mol/L.

Water steam reacts with oxygen difluoride producing mainly hydrogen fluoride and oxygen

The reaction is exothermic. At the conditions of a premixed burner similar to the one used for fluorine/steam flames, the components did not ignite spontaneously, but when properly initiated the reaction proceeded with a flame [106]. The burner used consisted of two concentric tubes. The inner tube was copper or stainless steel with an i.d. = 0.40 or 0.50 cm and a wall thickness of about 0.2 mm. The outer tube had an i.d. of 1.90 cm and was made of brass or Pyrex glass. Both steam and oxygen difluoride

were preheated to about 373 K (100 °C). The oxygen difluoride-steam diffusion flame was stable and weakly luminous.

2.4.4.2 Oxygen Difluoride/Hydrogen Reactions

The oxygen difluoride/hydrogen reaction is potentially useful in chemical lasers. The kinetics of the $\text{OF}_2 + \text{H}_2$ reaction was studied at 383–463 K (110–190 °C) in a flow reactor with helium dilution [107]. Oxygen at or in excess of 5 mol-% inhibited the reaction. This reaction had a significant heterogeneous component and is dependent on the reactor material.

The kinetics of the $\text{OF}_2 + \text{H}_2$ reaction in the temperature range of 383–493 K (110–220 °C) at 1 atm total pressure was studied in a Monel stirred-flow reactor with helium as the carrier gas [108]. The products approximate stoichiometry was represented the equation

The rate was strongly inhibited by oxygen and was unaffected by the other products. The reaction was first order with respect to oxygen difluoride.

The kinetics of the $\text{OF}_2 + \text{H}_2$ reaction was further studied in the temperature range of 433–583 K (160–310 °C) at 1 atm total pressure in a magnesium stirred-flow reactor with helium as the diluent [109].

2.4.4.3 Oxygenyl Fluoronium Salts

Oxygen difluoride may be used as the starting product for formation of oxygenyl fluoronium salts. These are potential rocket propellant or gas generant oxidizers. Dioxygenyl fluoronium salts are described in the section “Dioxygenyl(II) Complex Fluoride Salts”.

2.4.5 Analysis of Oxygen Difluoride

The reaction of OF_2 with mercury or potassium iodide can be used to analyze the assay of OF_2 samples [110, 111]; however, both reagents will also respond to free fluorine that may be contained in the OF_2 sample as a contaminant. For the quick and less sophisticated detection of OF_2 in the air in rocket test sites a gas detection tube has been developed that contains potassium bromide and fluorescein on a silica gel carrier. The reaction with OF_2 (or many other oxidizers) liberates bromine that converts fluorescein to eosin and produces a distinct color change [112]. The length of the colored zone is proportional to the quantity of oxygen fluoride. Optimum conditions for the determination were established.

Mixtures of OF_2 with NF_3 , CF_4 , SiF_4 , N_2 or O_2 can be analyzed by GC on a silica gel column which was dried and desorbed by first heating to 1173 K (900 °C) and then coated with 30% halocarbon oil and proved to be sufficiently resistant to the mostly

very aggressive gases, while still giving good separations. The retention volumes of a series of inorganic gases on this column were measured and the height equivalent to a theoretical plate (HETP) calculated [113].

Oxygen difluoride and other even more corrosive oxidizers can be analyzed by mass spectrometry in a mass spectrometer that was modified by removing all glass parts and replacing them with Monel and Teflon [114]. Oxygen difluoride mass spectra displayed rhenium oxyfluorides as the result of sample corrosive interaction with a rhenium filament in the source.

A GC method was used for purification of commercial OF_2 containing O_2 and CF_4 [115]. Components in GC effluent gases were determined and identified. Pure OF_2 was collected in a cold trap and subsequently used for calibration of mass and IR spectrometers and physical measurements.

Quantitative and qualitative analysis of OF_2 was possible by GC through a $1\text{ m} \times 0.25\text{-in.}$ copper column filled with 40–60 mesh silica gel, helium as carrier gas and a thermal conductivity detector, except that OF_2 and CF_4 were not separated [116]. The possible CF_4 content would have to be determined by IR in a separate analysis.

The adsorption of OF_2 on SH-functionalized $\text{B}_{24}\text{N}_{24}$ or $\text{B}_{24}\text{P}_{24}$ nanocages has been evaluated theoretically as a potential sensor for OF_2 detection in the gas phase, but this work lacks experimental verification [117].

2.5 Handling of Oxygen Difluoride

2.5.1 Materials of Construction for Oxygen Difluoride

The selection of materials of construction for OF_2 systems is relatively easy. At room temperature, the dry gas does not attack glass, quartz, or metals. It can be stored in glass vessels in the gaseous or liquid state. Vessels containing liquid OF_2 should be hermetically sealed from the atmosphere to prevent escape of OF_2 vapors and to prevent intrusion of atmospheric moisture.

All components for OF_2 use must be thoroughly cleaned and degreased before they come into contact with OF_2 . Once the system is assembled and leak-checked, it can be gradually passivated with either diluted elemental fluorine or OF_2 .

There are several good design manuals for OF_2 systems which contain detailed information on material compatibility and system design and operating instructions, such as cleaning and passivation [19, 20, 48].

2.5.1.1 Compatibility of Metallic Materials of Construction with Oxygen Difluoride

Most metals react with OF_2 only after they are heated to several hundred degrees C. Polished, shiny copper will tarnish when heated in OF_2 . Most metals such as stainless steel, copper, aluminum, Monel or nickel can be used for OF_2 service up to a temperature of 473 K (200 °C). Above this temperature the suitability of a metal has to be tested from case to case. Anodized aluminum has been used for parts that come

in contact only with gaseous OF_2 such as in pressurant lines or vent lines. Venturi orifices for OF_2 were made from CRES-303. Nickel or copper were used for injector heads in rocket engines operating on OF_2 oxidizer.

The corrosive attack is accelerated when materials are immersed in a rapidly flowing liquid at high pressure, or when bubbles in the flowing liquid impinge on the surface, thus preventing the maintenance of a passivating layer. A simple rotation of the specimen is not satisfactory for investigating corrosive attack at such high velocities because the liquid tends to move with the specimen, and the actual rate of liquid movement with respect to the metal surface is not definitely known. An apparatus was developed to conduct accelerated corrosion tests of materials with fluorine oxidizers at cryogenic temperatures. It consisted of a closed loop with a diaphragm pump inserted in a cryostat. Rapidly flowing OF_2 flowed through an orifice made of the test material and impinged on a coupon of the same material to see if immediate reaction or slow corrosion would take place. A number of structural alloys were selected from materials that had shown good corrosion resistance in long-term immersion corrosion tests. Test times ranged from 8 to 30 min. Tests with O_3F_2 in LOX were run in the same apparatus. A wide range of metals was tested for compatibility with flowing OF_2 in the gaseous or liquid state, including Al-1100-0, Al-2014-T6, Al-6061-T6, CRES-316, CRES-347, Ni-200, Monel-400, columbium, and Cufenloy 40A [118]. The effect of flow velocity on corrosion rate was most pronounced with Al-1100-0 and barely noticeable with Monel. Orifice diameters eroded and increased with the less compatible materials and erosion damage in the impingement area was obvious, but no immediate ignition took place.

The static corrosion rates of metals and alloys in fluorine-containing oxidizers at cryogenic temperatures are small due to the formation of passivation fluoride films. Low corrosion rates are difficult to measure with conventional methods since the total mass change is very small. The corrosion resistance of platinum, copper, nickel, and tantalum in liquid OF_2 was estimated from changes in solution capacitance and conductance between two plates of these materials [119]. Capacitance and electrical conductivity increased as the result of film formation and dissolution of metal ions. Both comparisons indicated that Ta was more susceptible to corrosion than Ni. A marked increase in capacitance and a decrease in solution resistance between Ta electrodes occurred when the temperature of OF_2 was increased from 117 to 181 K (-156 to -92°C). Therefore, an appreciable increase in corrosion attack of tantalum by OF_2 was to be expected at the higher temperatures. For comparison, the corrosion rates of metals in OF_2 determined by mass change measurements were given, as shown in Table 14.

Impact sensitivity, static immersion corrosion rates, susceptibility to stress corrosion, corrosion in flowing liquids and effects of weldments and impurities on corrosion of OF_2 in contact with various materials of construction were tested and the results of tests were presented in a form that should be useful to rocket designers [120, 121]. Three stainless steels, 301 (full hardened), 316 (annealed), and 347 (annealed) were stressed and exposed to OF_2 for 21 days at 194 K (-110°F). No stress corrosion

Table 14: Corrosion rate of metals in liquid oxygen difluoride at 194 K (−110 °F).

Material	Test duration				Test duration			
	1 Day	21 Days	4 Months	1 Year	1 Day	21 Days	4 Months	1 Year

Data source: [119; 120]

failure occurred. Three welded aluminum alloys were stressed to or beyond their yield strength (0.2% offset) and exposed to OF₂ for 21 days at 194 K (−110 °F) under a pressure varying from 342 to 580 psig. The test coupons were double tensile test specimens in geometry, with one end exposed to the gas and the other to the liquid phase. All specimens were observed to have a narrow band of corrosion attack next to the weld zone. The stressed 2219-T6 welded aluminum alloy failed in the section exposed to the gas phase. None of the other plastically deformed test coupons broke. Studies with impure oxidizer (OF₂ with 1% water addition) were conducted on aluminum alloys, magnesium alloy, columbium, tantalum, stainless alloys, copper, brass, nickel alloys, and titanium alloys. In general, corrosion was considerably accelerated, though not to the extent seen in earlier tests with moist N₂F₄—ClO₃F.

A survey of pretreatment methods for metal surfaces that are to come into contact with OF₂ and other storable propellants suggested that for most other oxidizers special pretreatment is not necessary as long as the surfaces are free of contaminants, but in the case of OF₂ and FLOX it may be advantageous to practice gradual exposure of metal surfaces to the fluorine compound to ensure deactivation of contaminants which may have resisted the cleaning process [122]. Details of a general procedure were given for pretreatment of metal systems to be used with OF₂, ClF₃, or FLOX: **(1)** descale, degrease, dry, and **(2)** deactivate residual contaminants with a controlled fluorination treatment. The recommended fluorination treatment is merely a step in the cleaning procedure and not a deliberate attempt to provide “passivation”. Passivation leads to the formation of protective fluoride films. The thickness and adherence of passivating fluoride films determines corrosion rates during long-term storage. Reports on the compatibilities and corrosion rates of metals and fluorine oxidizers were reviewed.

Crush gaskets can be made from soft copper. Pliable gaskets and O-rings can be made from Teflon. Perfluorinated oils can be used as lubricants. If one wants to measure low pressures with a U-gauge, mercury cannot be used as the manometer fluid because it reacts with OF₂. A layer of a perfluorinated oil may protect the mercury for short-term service.

Flow decay studies examined clogging materials not only in oxygen difluoride, but also in dinitrogen tetroxide (NTO), hydrazine, and diborane, all in the category of space-storable propellants [123, 124]. Liquid oxygen difluoride was flowed through a 0.25-mm (0.010-in.) diameter orifice, a 2–10 μm filter and a 10- μm surface tension acquisition screen, but showed no evidence of flow clogging or flow decay [125]. The propellant was run both neat and doped with contaminants in a controlled way for the orifice and filter test runs. Temperature conditioned runs ranged from 155 to 122 K (–180 to –240 °F). Approximately a 10% variation in flow was noted during a single run for several runs. Some difficulty was experienced in controlling flow. In several runs flow rate increased and then decreased and increased again indicating erratic flow control. The flow control may be inherent in the flow bench or instrumentation. Temperature variations may have been responsible causing changes in density and viscosity; however, in all cases, no trends were apparent which indicated flow clogging or flow decay behavior of oxygen difluoride.

Radioactive tracer test methods that were successfully used to study metals corrosion in N_2O_4 can possibly also be used for OF_2 [126–128]. See also [129, 130].

2.5.1.2 Compatibility of Non-metallic Materials of Construction with Oxygen Difluoride

Fluorocarbon plastics and silicone rubber are suitable for use with OF_2 , and Teflon, polyethylene, and ethylene propylene rubber can withstand a perchloryl fluoride-tetrafluorohydrazine mixture for a short time [131].

Shock sensitivity tests showed that both Teflon and graphite in OF_2 at 194 K (–110 °F) could be exploded with a planar shock wave of 827 MPa (120000 psi), but no reaction took place at 620 MPa (90000 psi) or at 77 K (–320 °F) [120, 132].

Preliminary compatibility experiments have shown that silica filler in conventional elastomer compositions provided a site for progressive attack by OF_2 . To improve the resistance of *cis*-1,4-poly(butadiene) elastomers to attack by OF_2 at low temperatures, it was therefore attempted to replace the silica filler with less reactive substances, for example, alumina [133]. An elastomer was compounded with “fumed” alumina, i.e., submicron alumina produced by condensation of alumina formed in a vapor phase hydrolysis reaction. Dynamic tests (tensile strength and elongation at break in propellant) showed the new elastomer compound to be especially rugged, even at 194.6 K (–78.5 °C). Long-term compatibility tests showed that both relaxed and stressed elastomer compounds did not undergo significant degradation in OF_2 and, moreover, the compound had a very low permeability coefficient at 194.6 K (–78.5 °C).

2.6 Disposal of Surplus Oxygen Difluoride

The disposal of surplus OF_2 uses methods similar to those recommended for elemental fluorine. The gas can be diluted with air or nitrogen and then fed into a fuel-rich

methane or propane flame. If the activated charcoal disposal method is used, the charcoal canister has to be preheated externally because the reaction with OF_2 does not start by itself at room temperature. The stack gases of either disposal reactor must be tested periodically with potassium iodide-starch paper for the presence of unreacted OF_2 or F_2 . The USAF has tested OF_2 propellants at Arnold AFB in Tennessee and reported on experience in handling and disposal of OF_2 at rocket test sites [134].

2.7 History of Accidents with Oxygen Difluoride

One phase of a materials compatibility test program consisted of immersion of structural materials in gaseous and liquid OF_2 for short periods of 1 and 21 days, and for longer periods of 4 and 12 months in a dry ice bath at 195 K (-109°F) at a saturation pressure of 3.44 MPa (500 psi). On 15 October 1963, during maintenance of the immersion baths of the long-term test containers, an explosive reaction or deflagration occurred [135]. It was confined to one test bay but resulted in the destruction of the long-term immersion test set-up and caused severe physical injury to the research technician attending to the immersion bath in the test bay. The accidental explosion which resulted in the destruction of the immersion test set-up and severe personal injury occurred while the research technician was replenishing the cold bath with crushed dry ice. Four long-term exposure tests were in progress in the test bay on the day of the accident. Two of them (both exploded) were tests involving OF_2 , and two involved a mixture of 50% perchloryl fluoride–50% tetrafluorohydrazine. The latter ones did not explode. The technician later reported that he felt a tremendous blow and a sensation like a strong electric shock. The ladder was blown from under him, and he was knocked down to the floor of the bay. His boots, shirts, and part of his trousers pants were blown off, and both legs and one arm received severe injuries. He was taken to hospital in a critical condition. There were two distinct explosions approximately 1/10 s apart. This was heard by persons away from the test facility; the technician and the project scientist did not perceive two separate blasts. A violent physical jolt and a flash of light accompanied the detonations. Both OF_2 exposure tests had been destroyed, and fragments of the test bombs and test coupons were strewn over a wide area. From the condition of the Teflon pieces used as a rack to hold the immersed metal samples, it appears that this material was involved in a reaction with oxygen difluoride

This reaction is highly exothermic and gives 4.6 kcal/formula weight. See also reference [136].

2.8 Gelled Oxygen Difluoride

In an effort to reduce the leakage hazard of liquid oxygen difluoride and at the same time improve its ignition characteristics and rocket engine performance, a variety of gelling agents have been tested with OF_2 , including frozen ClF_3 . Chlorine trifluoride is not soluble in liquid OF_2 and microcrystalline, finely dispersed solid ClF_3 suspended in liquid OF_2 can create a gelled propellant with high viscosity [137–140]. During the development, ClF_3 -gelled liquid nitrogen was used as a more inert simulant for the ClF_3/OF_2 gel. It was found that liquid nitrogen gelled with solid chlorine trifluoride possesses static and dynamic flow properties which closely approximate those of the OF_2/ClF_3 gels. Thus, LN_2/ClF_3 gels may be used as suitable simulants for OF_2/ClF_3 gels. The ClF_3/OF_2 gel was found to be chemically and mechanically stable in static tests. Samples of the gel were stored for 30 days. ClF_3 as a volatile gellant has the advantage over fumed silica that it will not leave residues which might clog the injector orifices. Other gelling agents (not using ClF_3) were developed for gelling of B_2H_6 [141].

Inorganic fluorides and oxides were screened as potential gelling agents for OF_2 . Liquid OF_2 was gelled with Alon C, fumed TiO_2 , and Cab-O-Sil fumed silica [142]. The best gel properties were obtained with Cab-O-Sil. Gel samples were evaluated for thermal stability, mechanical stability, evaporation rate relative to ungelled OF_2 , and shock sensitivity. It was later found that OF_2/SiO_2 gels are potentially explosive [143].

Another gelling agent tested was finely divided lithium fluoride with particle lengths of $0.4\text{ }\mu\text{m}$ [144]. The liquid OF_2/LiF gel was thermally stable and shock insensitive but was not stable under flow conditions in a rheometer.

Other gelling agents proposed for non-metallic fluoride liquid oxidizers were barium hexafluoroantimonate and barium hexafluorobismuthate [145].

2.9 Toxic Properties of Oxygen Difluoride

Oxygen difluoride is assumed to pass intact into the pulmonary cells where it reacts with biochemical reducing systems to ultimately cause cell death and structural failure. OF_2 is fairly stable in aqueous systems and would be expected to survive chemically in the atmosphere of the lungs and in the gas transport processes without immediate reaction on pulmonary surfaces. It is soluble enough ($608\text{ mL OF}_2/\text{L}$ of water at $273\text{ K} = 0^\circ\text{C}$) to permit transport into cells in the low amounts evidently necessary for lethal effects. OF_2 degasses quickly from saturated aqueous solutions when its partial pressure in the atmosphere falls. In the course of an exposure, the gas should therefore be present in the lungs only during the period of exposure, leaving a minor amount of HF resulting from the limited reaction of OF_2 with the aqueous phase of the pulmonary membrane complex.

Oxygen difluoride is very toxic and must be handled with the same precautions as elemental fluorine. In some instances, it has been observed that OF_2 is actually more

toxic than F_2 . Ruff and Menzel [17] attributed this to the fact that OF_2 initially dissolves in the tissue and diffuses to the lower layers before it hydrolyzes and unfolds its toxic action, whereas with elemental fluorine the action is limited to the surface and the tissue forms a scar layer. Inhalation of an aerosol of calcium chloride or magnesium acetate solution has been recommended as a first aid measure in the treatment of OF_2 victims. The olfactory threshold of OF_2 in air is 0.1 ppm and it can be recognized by its odor at 0.5 ppm. Based on animal tests with rats, the LC50 after a 5-min inhalation was 20 ppm, and after a 20-min inhalation it was 5 ppm [146, 147]. Chronic inhalation of 0.5 ppm OF_2 in rats caused some casualties. Chronic long-term inhalation tests with rats (6 h/day, 5 days/week, cumulative exposure of 165 h) at 0.1 ppm OF_2 did not cause any adverse effects. In order to maintain sufficient margin of safety, it is recommended to keep the working place concentration below 0.005 ppm [148]. There are analytical instruments available that can detect fluorine and OF_2 at very low levels.

The acute inhalation toxicity of oxygen difluoride in the albino rat has been determined at concentrations of 5–40 ppm for 5–15 min [149]. A concentration $\times$ time (CT) product (ppm-min) of about 100 results in 50% mortality. At the levels studied, gross and microscopic pulmonary damage developed 7 h after termination of the exposure, and, if death did not intervene, repair began after the third day. The extreme toxicity of oxygen difluoride and its insidious character make it imperative to exclude any potential for inhalation by personnel in the laboratory.

Oxygen difluoride exposures of groups of rats were made in an $18 \times 18 \times 27$ in. aluminum chamber fitted with transparent Kel-F view ports and lined with Teflon-surfaced glass cloth [150, 151]. Groups of 10 rats were exposed to 15 ppm (by volume) OF_2 for 10, 15, 22.5 or 34 min and observed for up to 5 days afterwards. The survival time was measured and ranged from 2 to 37 h (and a few survivors at 5 days) in the 10-min group and from 0.2 to 5.7 h in the 34-min group. Groups of 4 rats were exposed to 30 ppm OF_2 for 10, 15 or 22.5 min and survival times ranged from 3 to 4 h in the 10-min group (no survivors) and 0.3–3.6 h in the 22.5 min group (no survivors). Tissue and blood samples were taken from deceased and surviving animals and analyzed for fluoride content. Clinical chemistry observations showed little change over a 20-h period following OF_2 exposure for 10 min at 15 ppm. This dose was high enough that a few animals of the series observed died before they could be sampled. Blood glucose rose moderately and remained somewhat higher than normal for the entire period of observation. The limited damage found in organs and tissues other than the lungs indicated that OF_2 had not achieved more than limited distribution, but reacted primarily in the pulmonary cells.

Four species of animals (monkeys, dogs, rats, and mice) were exposed to various concentrations of 8, 16, 21, and 32 ppm OF_2 in air for 15 or 60 min [152]. The acute effects of OF_2 inhalation were shown mainly to be respiratory in nature. Tachypnea was the most prominent toxic sign observed in rodents. Upper respiratory and gastrointestinal tract irritations were observed in dogs and monkeys. The mortality response demonstrated a significant difference in the susceptibility of the various species to

Table 15: Mortality LC50 for oxygen difluoride inhalation in four animal species.

Animal species	LC50, ppm by volume		CT dose, ppm × min	
	60 Min	15 Min	60 Min	15 Min
Mouse	1.5	7.5	90	113
Rat	2.6	12.7	156	191
Dog	26	90	1560	1350
Monkey	26	108	1560	1620

Data source: [152]

the toxic effects of the gas. Rats and mice were found to be much more susceptible than monkeys or dogs (Table 15). In mice a certain amount of tolerance developed if the animals were conditioned in 1 ppm OF₂ for 1–7 days prior to a 1–8 day exposure to 3.5–4.25 ppm which produced some mortality. There was no tolerance developed in animals preconditioned at 0.25 or 0.5 ppm prior to the more severe exposure.

The lungs of rats exposed to OF₂ were examined by light and electron microscopy [153]. The exposures were for 30–60 min to an average of 4.5 ppm OF₂, the minimal lethal dose. Animals were sacrificed after 30 (group 1) and 60 min (group 2) exposure and 1 (group 3) and 2h (group 4) following 60 min exposure. Mild gross changes were observed in groups 3 and 4, but no light microscopic visible lesions were found. Alterations were noted in all four groups using electron microscopy. These were mostly indicative of fluid change and consisted of blebbing of the endothelial and epithelial layers of the alveolocapillary wall and rarefication of the cytoplasm of these cells. The lamellar bodies of the type II cells showed an increasing and consistent loss of matrix structure and density. These fine structural changes increased in quantity and severity as time of exposure or post-exposure period increased.

In about 1968, a student was transferring OF₂ vapor from a 1-lb tank to his apparatus through Tygon tubing that had been cleaned with benzene, but the tubing ignited and the tank fell on the floor, bending the shut-off valve while gas was still leaking. The student went to a workbench to grab a wrench and shut the valve, but by then most of the gas had leaked out. The student was sent to a hospital and developed severe lung edema and was put on oxygen when he had trouble breathing. The lung edema resolved after 3 days and the patient was released from the hospital after 10 days. It was estimated that he had breathed 1000 ppm for 2–3 min which by all estimates should have been fatal. Other people in the building were exposed to smaller concentrations as the gas diffused through the building but they did not need hospitalization [154].

Raw toxicity data of inhalation toxicity tests with mice, rats, guinea pigs, and rabbits are summarized in Table 16.

The acute toxicity data for oxygen difluoride are summarized again in Table 17, including some of the data already referenced individually above.

Table 16: Inhalation toxicity of oxygen difluoride.

Concentration ppm	Duration h	Mortality, %			
		Mice	Rats	Guinea pigs	Rabbits
10	1.0	7	8	15	0
10	1.5	20	100	50	0
10	2.0	74	100	90	0
10	2.5	100	100	100	0
10	3.0	100	100	100	25

0.5	28.75	—	10	—	—

Data source: [155]

Table 17: Acute toxicity data and lethal concentration data of oxygen difluoride.

Species	LC50 (ppm)	Duration	Adjusted 0.5–h LC (CF)	Derived value
Rat	2.6	1 h	3.3 ppm (1.25)	0.3 ppm
Mouse	1.5	1 h	1.9 ppm (1.25)	0.2 ppm
Dog	26	1 h	33 ppm (1.25)	3.3 ppm
Monkey	16	1 h	20 ppm (1.25)	2.0 ppm

Data source: [156, 157]

The recommended maximum tolerable concentrations of OF₂ in workroom air are: NIOSH REL: 0.05 ppm (0.1 mg/m³) ceiling; OSHA PEL: 0.05 ppm (0.1 mg/m³) TWA; 1989 OSHA PEL: 0.05 ppm (0.1 mg/m³) ceiling; 1993–1994 ACGIH TLV: 0.05 ppm (0.11 mg/m³) ceiling [158]. At one time the National Research Council (NRC) Emergency Exposure Limits (EELs) recommended to military and space agencies were: 10-min EEL: 0.5 ppm; 30-min EEL: 0.2 ppm; 60-min EEL: 0.1 ppm. The NIOSH revised IDLH was 0.5 ppm.

2.10 Detonability Properties of Oxygen Difluoride

Oxygen difluoride is not shock sensitive. Tests using Trauzl block techniques indicated that OF_2 is insensitive to shock at 77 K (-196°C). The cavity volume of the lead block increased 40%, which is more than with a blank test with water (17%), most likely due to a chemical reaction between the OF_2 and the lead. For comparison, the cavity volume increase with RDX was 130%. A cylinder of liquid OF_2 was subjected to a bullet impact test which ruptured the cylinder but failed to detonate the OF_2 [159].

3 Dioxygen Difluoride

Dioxygen difluoride, O_2F_2 , $\text{F}-\text{O}-\text{O}-\text{F}$, oxygen subfluoride, perfluoroperoxide, dihydroxydifluoride, dioxydifluoride, CAS RN [7783-44-0] is not very stable and cannot be used as a rocket propellant. It is included in this book only as an intermediate in the synthesis of other fluorine oxidizers or as a decomposition product of higher multi-oxygen fluorides. There is a lot of interest in trioxygen difluoride (“ozone fluoride”) as a means to hypergolize LOX, and O_2F_2 is either a byproduct of O_3F_2 preparation or the end product of O_3F_2 or O_4F_2 decomposition. This is why this chapter on O_2F_2 was added to this book at this point. Dioxygen difluoride has received a lot of attention from atmospheric chemists because a free radical derived from O_2F_2 , the free radical $\cdot\text{OOF}$ is suspected of playing a role in the ozone layer destruction in the upper atmosphere of Earth where it forms in the photolysis of man-made fluorocarbons that leaked from refrigeration units and cosmetic aerosol sprays. $\cdot\text{OOF}$ is relatively stable and there are more publications on $\cdot\text{OOF}$ than on O_2F_2 itself.

3.1 Preparation of Dioxygen Difluoride

Dioxygen difluoride, O_2F_2 forms as an orange liquid if one passes a equimolar mixture of oxygen and fluorine at 2000–2660 Pa (15–20 mm Hg) and 83 K (-190°C) through a glow discharge [160, 161]. The formation of dioxygen difluoride from the elements in a glow discharge was investigated at a pressure of ~ 1 mm Hg, current strengths 10, 20, and 40 mA, and gas velocities from 0.4 to 11 L/h [162–164]. The amount of O_2F_2 obtained was proportional to the volume velocity of the gases. The dependence of the degree of conversion on the fluorine-oxygen mixture ratio and specific energy was established. A stationary value of the degree of conversion for these experiments is reached at a specific energy of ~ 30 Wh/L. A scheme of formation of dioxygen difluoride in a discharge was proposed.

The destruction of the ozone layer in Earth’s stratosphere as the result of halocarbon atmospheric pollution involves reactions of $\text{FO}\cdot$ and $\text{FOO}\cdot$ radicals. The photochemical reaction of F_2 and O_3 was studied at 195 and 120 K in order to test for the

presence of the $\text{FO}^\bullet$ radical [165]. The product composition was dependent on operating temperature. In experiments at 120 K, a gaseous mixture of F_2 and O_3 was UV-irradiated at 3660 Å for 4 h. After irradiation, the reaction vessel contained a colorless gas and a yellow deposit on its walls, and the gas consisted of OF_2 , O_2 , and F_2 . O_3 was no longer detected. The yellow deposit was soluble in CClF_3 . An electron paramagnetic resonance (EPR) spectrum of the solution was identical with a solution of O_2F_2 , namely that of the $\text{FOO}^\bullet$ radical. The yields of O_2F_2 and OF_2 were 36 and 20%, respectively. In additional experiments at 195 K, irradiated mixtures of F_2 and O_3 yielded only OF_2 , and O_2F_2 was not detected.

Dioxygen difluoride can be prepared by photosynthesis directly from the elements by illuminating a liquid mixture of oxygen and fluorine with UV light at 77 K (−196 °C) [166].

Low-energy pathways of the reaction $\text{F}_2 + \text{O}_2 \rightarrow \text{O}_2\text{F} + \text{F}$ or O_2F_2 through excitation of F_2 or O_2 in a frozen oxygen matrix were measured as a function of laser irradiation frequency [167]. The F_2 absorption detected in this experiment extended more than 200 nm to longer wavelengths than any electronic absorption of molecular difluorine reported so far.

When $\text{F}^\bullet$ atoms produced by a microwave discharge through NF_3 in argon carrier gas were codeposited with O_2 in an argon matrix at 14 K, prominent IR absorptions, including several overtone and combination bands of $\text{FO}_2^\bullet$ and of O_2F_2 were found [168].

Dioxygen difluoride is not alone with its X_2O_2 structure in the family of halogen oxides. The other halogen oxides and their ions and radicals are also known and their structures have been compared to that of O_2F_2 [169].

The plasma chemistry in an O_2/F_2 low-pressure high-density discharge and the plasma parameters, electron temperature T_e , DC plasma potential V_{pl} , electronegativity as well as the densities of the reacting species were calculated as a function of F_2 content and discharge pressure in the pressure range 0.13–13 Pa (1–100 μm Hg) [170]. The difluorine is highly dissociated. The prevalence of fluorine atoms increased as F_2 was added to the discharge and for mixtures with ~35% F_2 atomic fluorine $\bullet\text{F}$ was the dominating species in the discharge. The dominant positive ions changed from O^+ and F^+ at low pressure (<0.67 Pa = <5 μm Hg) to O^{2+} and F^{2+} at high pressure (>6.7 Pa = >50 μm Hg).

Dioxygen difluoride (O_2F_2) can be produced directly in the liquid phase at temperatures above 119 K (−154 °C) [171]. An O_2/F_2 gas mixture was heated to 973 K (700 °C) and was then rapidly cooled on the outer surface of stainless steel cold fingers refrigerated by a liquid oxygen bath pressurized to >1 MPa with helium. This produced 6 g of O_2F_2 in less than 1 h. Color of the viscous liquid in the O_2F_2 generator ranged from copper red to straw yellow. Different O_xF_y compounds existed simultaneously on the tubes. Audible “pings” and pressure excursions occurred when liquid O_2F_2 was dripped onto uncooled portions of the apparatus and decomposed spontaneously.

Several low-temperature oxygen fluorides that are stable only at cryogenic temperatures were synthesized and their mass spectra were studied between 77 and 260 K, but neither the parent ion of O_2F_2 , O_3F_2 or O_4F_2 nor the unambiguously assignable fragment ions of O_3F_2 or O_4F_2 were observed [172]; however, the appearance potentials of O_2F^+ and OF^+ were measured to be 14.0 eV and 17.6 ± 0.2 eV, respectively, at 130 K. These values were consistent with other related data and indicated that these ions were produced by electron impact fragmentation of O_2F_2 .

3.2 Physical Properties of Dioxygen Difluoride

Dioxygen difluoride is not very stable and decomposes even at 223 K (-50°C) in reversal of its formation. Because it decomposes so rapidly, the boiling point of this compound could not be determined by direct measurement, but it had to be extrapolated from vapor pressure curve measurements up to 216 K (-57°C). The orange color of the condensate can give rise to confusion with other O_xF_y compounds, such as trioxygen difluoride O_3F_2 that forms under the same conditions but is obtained by starting with a different $\text{F}_2:\text{O}_2$ ratio. Other differences between the two compounds are the melting points (O_2F_2 m.p. 109.6 K = -163.5°C ; O_3F_2 m.p. 82.2 K = -190.9°C) and the densities (O_2F_2 ρ_{liq} at 216 K = -57°C : 1.45 g/cm³; ρ_{solid} at 108 K = -165°C : 1.912 g/cm³, O_3F_2 ρ_{liq} at 90 K = -183°C : 1.756 g/cm³). Because of its lack of thermal stability, O_2F_2 is not useful as a rocket propellant. Nevertheless, we are summarizing here some of its properties because O_2F_2 may serve as an intermediate in the synthesis of other oxygen fluorides or it is encountered as a decomposition product of some of the other polyoxygen fluorides.

Pure O_2F_2 is an orange solid melting at 109.7 K. It is thermally unstable and decomposes to oxygen and fluorine in the neighborhood of its boiling point at 216 K.

3.2.1 Optical Properties of Dioxygen Difluoride

In the visible/UV spectrum, the maximum absorption of O_2F_2 at 140 K is at 360 μm . It changes color with temperature.

The infrared spectrum of solid O_2F_2 , produced by radiolysis of a mixture of liquid O_2 and F_2 , has been obtained at 77 K [173]. With the help of isotopic labeling, all fundamental vibrations could be located and assigned. The results showed that the O—O bond in O_2F_2 has considerable double bond character, resembling O_2 more than it does H_2O_2 , and having a significant barrier to internal rotation. There is considerable participation of the fluorine p electrons in the bonding orbitals.

A complete absorption spectrum of gaseous dioxygen difluoride was obtained using a very long path length, temperature-programmable cell and an FT-IR spectrometer [174]. All six fundamental vibrational frequencies were deduced from three fundamental bands and four binary combination bands. A significant deviation of the ν

frequency was observed from the matrix studies of solid FOOF. All data indicated that O_2F_2 is a linear molecule and does not exist in the branched $\text{O}=\text{OF}_2$ form.

The unusual bond lengths in FOOF were compared to the structure of FNNF in an effort to explain the electronic structure of σ -bonds and π -bonds in these molecules [175]. If a double-quartet modification of the octet rule is used, ten structures, including semipolar bonds, would be possible for this molecule, assuming that around every atom, the four electrons of a given spin have a tetrahedral arrangement. Structures are favored that (a) have small formal charges on the atom, and (b) reduce interelectron repulsion. Formal charges of $+1/2$ and $-1/2$ on oxygen and fluorine would seem to be allowable energetically.

Photolysis of F_2 and O_2 suspended in solid N_2 , Ar or O_2 produced IR absorptions of an oxyfluoride other than OF_2 and O_2F_2 [176]. Isotopic labeling, concentration dependence, diffusion behavior, and normal coordinate analysis permitted assignment of these bands, at 1499.7, 586.4, and 376 cm^{-1} , to the free radical or cation O_2F . On diffusion at low temperatures, this molecule formed only loosely bound aggregates, $(\text{O}_2\text{F})_n$, though it is a free radical. Normal coordinate analysis showed that the O—O bond of O_2F is a double bond, like those in O_2 and in O_2F_2 and that the O—F bond is much weaker than those in OF_2 . Thus, O_2F resembles O_2F_2 in its bonding.

3.2.2 Magnetic Properties of Dioxygen Difluoride

The chemical shift of ^{19}F in O_2F_2 is unusually low. A dilute solution of O_2F_2 in CF_3Cl showed a single peak at 865 ± 10 ppm. The peak position relative to that of CF_3Cl did not change much with temperature in the range 193–143 K (-80 to -130°C). Dioxygen difluoride contains a paramagnetic species ($\bullet\text{OOF}??$). Exchange between $\bullet\text{OOF}$ and FOOF could explain the line shift and also the line width of the NMR signal. It was concluded that either no exchange is taking place, or that the concentration of free radicals is much too low to greatly affect the NMR spectrum [177].

The ^{19}F NMR spectra of liquid O_2F_2 were already discussed in the OF_2 section [86]. The shifts of O_2F_2 and O_3F_2 were the furthest downfield of any simple fluorine compound yet reported.

3.2.3 Thermodynamic Properties of Dioxygen Difluoride

Thermodynamic properties of O_2F_2 were included in earlier tables where it was listed along with the other oxygen fluorides. A very detailed summary of thermophysical properties of O_2F_2 is available in [12] and [178]. The most recent recommended value for the standard enthalpy of formation of O_2F_2 gas was $-19.163\text{ kJ/mol} = -4.58 \pm 0.2\text{ kcal/mol}$. The data for ΔH_f and ΔG_f in the Lyman paper may be too low by 5.65 kJ/mol . Other sources [4] give the heat of formation as $+4.73 \pm 0.30\text{ kcal/mol}$.

The NIST-JANAF thermochemical table values for the thermochemical properties of oxygen fluorides issued in 1996 were critically examined on the basis of high-level density functional and *ab initio* G2 calculations [55]. Special attention was given to the

enthalpies of formation and it was concluded that although the proposed values for $\text{OF}(\text{G})$, $\text{FOO}(\text{G})$, and $\text{FOF}(\text{G})$ are reasonable and in agreement with previously recommended values, the enthalpy of formation recommended for FOOF is too low. Instead, a value about 50% larger was proposed and it was recommended that the original 1959 experimental determination of this enthalpy of formation should be repeated.

3.2.4 Molecular Structure of Dioxygen Difluoride

The vibrations and microwave absorption spectra lines of O_2F_2 were assigned by isotope labeling and demonstrated that the structure is a chain, $\text{F}-\text{O}-\text{O}-\text{F}$, with the structural parameters: $r(\text{O}-\text{O}) = 1.217 \pm 0.003 \text{ \AA}$, $r(\text{F}-\text{O}) = 1.575 \pm 0.003 \text{ \AA}$, $\angle\text{OOF} = 109^\circ 30'$, and dihedral angle $= 87^\circ 30'$ [179]. The $\text{O}-\text{O}$ distance is particularly short and the $\text{O}-\text{F}$ distance is particularly long. The oxygen-oxygen distance $r(\text{O}-\text{O})$ in OF_2 is much shorter than in H_2O_2 and $r(\text{O}-\text{F})$ is much longer than in OF_2 . The fact that $r(\text{O}-\text{O})$ in OF_2 is very similar to that found for the dioxygen molecule indicated that there must be some multiple bonding between the two atoms. The barrier to internal rotation must be fairly high. The dipole moment of the molecule as derived from measurements of the Stark effect was $1.44 \pm 0.04 \text{ D}$.

The structure of O_2F_2 is a non-linear $\text{F}-\text{O}-\text{O}-\text{F}$ chain with an $\angle\text{OOF}$ angle of $109^\circ 30'$, a dihedral angle of $87^\circ 30'$, an $\text{O}-\text{O}$ bond length of $1.217 \text{ \AA}$, and an $\text{F}-\text{O}$ bond length of $1.575 \text{ \AA}$. Infrared spectra help to determine the molecular structure and the bond energies in the gaseous O_2F_2 molecule [174]. All data indicated that O_2F_2 is a linear molecule and does not exist in the branched $\text{O}=\text{OF}_2$ form.

Equilibrium structures of $\bullet\text{OOF}$, FOOF , OOF_2 , and FOOOF calculated using the density functional theory (DFT) methods were compared with those generated using the *ab initio* calculations and when possible the experimental data [180].

According to some other DFT calculations, the affiliation of lone pair electrons toward the fluorine atom decreased from OF_2 to O_3F_2 as the number of oxygen molecules increased [181]. The strength of $\text{O}-\text{O}$ bond decreased from O_2F_2 to O_3F_2 . The shorter $\text{O}-\text{F}$ bond of O_3F_2 could readily change to longer one and *vice versa* through a transition state with energy barrier of 11.06 kJ/mol . The $\text{O}-\text{F}$ bond is much stronger than the $\text{O}-\text{O}$ bond in O_3F_2 . On the contrary, the $\text{O}-\text{F}$ bond is much weaker than the $\text{O}-\text{O}$ bond in O_2F_2 . O_2F and O_3F can be regarded as weakly bound $\text{OO}-\text{F}$ and $\text{OO}-\text{OF}$ adducts, respectively. O_3F_2 could be regarded as a weakly bound $\text{FO}\cdots\text{OOF}$ adduct. The standard enthalpies and free energies of formation for the binary compounds can be predicted, but experimental verification is lacking in most cases.

3.3 Chemical Properties of Dioxygen Difluoride

3.3.1 Decomposition of Dioxygen Difluoride

Dioxygen difluoride is said to decompose into fluorine and oxygen with a half-life time at 223 K (−50 °C) of 3 h for the homogeneous unimolecular decomposition. The decomposition and many reactions of O_2F_2 and the higher multi-oxygen fluorides O_nF_2 , $n > 2$ involve the dioxygen fluoride $\bullet O_2F$ free radical as an intermediate. The free radical has been characterized by ESR. It may also play a role in the reaction of fluorine with ozone in the upper atmosphere. The ESR spectrum of $\bullet O_2F$ was found to contain normally “forbidden” lines in which the electron spin transition is accompanied by a nuclear spin flip [182].

Electron paramagnetic resonance spectra of O_2F_2 and O_3F_2 both showed identical EPR spectra which could be attributed to the free radical $\bullet OOF$, the concentration being 0.1 and 5 mol %, respectively [183]. In either system the radical is formed as the result of the ongoing decomposition process.

The reactions of fluorine atoms with dioxygen produce (and consume) the species $\bullet OOF$ and O_2F_2 [184]. The fluorine atoms can be produced by photolysis of molecular fluorine with an excimer laser (KrF, 248 nm).

The decomposition of gaseous dioxygen difluoride (FOOF) and dioxygen fluoride $\bullet OOF$ to F_2 and O_2 at ambient temperature has been studied by EPR spectroscopy, Fourier transform infrared (FTIR) spectroscopy and transient gas pressure measurements [185]. EPR spectroscopy detected neither F atoms nor $\bullet OOF$ radicals as intermediates despite the presence of $\bullet OOF$ radicals shown by complementary FTIR experiments. The FTIR spectra of gaseous FOOF undergoing decomposition at ambient temperature showed prominent, isolated bands near 1210 cm^{-1} (FOOF) and near 1490 cm^{-1} ($\bullet OOF$). Oxygen-carrier FTIR experiments strongly suggested that a reversible reaction between FOOF and O_2 forms $\bullet OOF$, and that this reaction was rapid relative to FOOF/ $\bullet OOF$ decomposition.

The equilibrium between dioxygen monofluoride $\bullet OOF$, dioxygen difluoride FOOF, and dioxygen O_2 has been studied in the temperature range 286–195 K and forward and reverse reaction rate constants were determined [186]. An activation energy of 54.4 kJ/mol (13 kcal/mol) was found for both reactions. The equilibrium constant in the middle of the temperature range was 21.5. The estimated heats of formation of gaseous $\bullet OOF$ and FOOF were +10.9 and 18.8 kJ/mol (+2.6 and +4.5 kcal/mol), respectively.

3.3.2 Reactions of Dioxygen Difluoride

Dioxygen difluoride can undergo a wide range of reactions with inorganic and organic reactants [187–189]. Liquid O_2F_2 reacted vigorously when added to solid anhydrous ammonia at temperatures close to 110 K. It caused explosions when added to water ice

at 130–140 K and reacted also with traces of water if dissolved in HF containing H₂O at 195 K, the brown color of the solution disappearing and O₂ gas escaping.

Investigations of the chemical reactions of O₂F₂ and other oxygen subfluorides were made in an effort to discover new reactions leading to solid oxidizers containing oxygen and fluorine [190].

Two new oxygen fluorides, O₅F₂ and O₆F₂, were discovered and methods of preparation and some of the properties of these new oxygen fluorides were described [191, 192]. Synthesis of polyoxygen difluorides by electrical discharge in the liquid phase or ultraviolet irradiation was accomplished. Thermal stability, sensitivity, solubility, and the EPR spectrum for O₅F₂ were determined. Free radicals play an important role in synthesis and decomposition of oxygen fluorides. Chemical reactions of O₄F₂ and N₂F₄ with O₃ were studied and additional data on solubility of O₄F₂ in LOX of liquid OF₂ were obtained. Diffusion flames of OF₂ with various fuels were obtained and characterized. Attempts were made to synthesize OF₄, which were so far unsuccessful.

Chlorine monofluoride ClF abstracts the fluorine from O₂F₂, forming ClF₃ and liberating O₂. The reaction of O₂F₂ with ClF showed that if the reaction is carried out without special precautions at temperatures above 140 K, the two substances react violently with heat evolution following the stoichiometric equation:

A deep violet compound was obtained by the reaction of O₂F₂ with ClF at 240–119 K (–33 to –154 °C). This compound was a strong oxidizer and was stable at 195 K (–78 °C). It was soluble in anhydrous HF at 195 K (–78 °C) and was not an electrolyte. Its thermal decomposition was suppressed by oxygen. Based on the observed stoichiometry of the overall reaction

the violet compound was postulated to have the composition (ClF₃O₂)_n. The same material was also obtained by the interaction of O₂F₂ with Cl₂ or HCl or by UV photolysis of mixtures of ClF₃ and O₂ at –78 °C [193].

Being a high energy oxidizer, dioxygen difluoride reacted vigorously with organic compounds, even at temperatures close to its melting point. It reacted instantaneously with solid ethyl alcohol, producing a blue flame and an explosion. When a drop of liquid O₂F₂ was added to liquid methane cooled at 90 K, a white flame was produced instantaneously, which turned green upon further burning. When 0.2 mL of liquid O₂F₂ was added to 0.5 mL of liquid CH₄ at 90 K, a violent explosion occurred.

In trying to identify differences in the reactive behavior of O₂F₂ and O₃F₂, each of these compounds was reacted with sulfur dioxide or nitrogen dioxide. This does not make a good rocket propellant, but it helped to understand the differences in reactivity of these two compounds [194, 195]. The reaction of SO₂ with O₂F₂ produced SO₂F₂ and byproducts FSO₂OF and FSO₂OOF. The products of the reaction of O₃F₂ with SO₂ were essentially the same as those obtained with O₂F₂, except that the relative quantities

were different. The mechanism of the formation of these products was studied by the use of NMR analysis of the compounds. The reaction of NO_2 with O_2F_2 did not produce FNO_3 , but only simple fluorination occurred, resulting in FNO_2 .

When running similar experiments with O_4F_2 in comparison to O_2F_2 , a comparison of the products formed in the reaction of SO_2 with O_2F_2 and O_4F_2 showed that the major product in both cases was F_2SO_2 , but the yield was lower in the O_4F_2 reaction [196, 197]. The yield of $\text{F}_2\text{S}_2\text{O}_5$ in the O_4F_2 reaction was also considerably lower than in the O_2F_2 reaction. Perhaps the most interesting observation was the comparison of the yields of FSO_2OOF (5% from O_2F_2 and 32% from O_4F_2). It was concluded that the primary reactions of both O_2F_2 and O_4F_2 are similar, i.e., simple fluorination predominates; however, O_4F_2 appears to be a better source of $\cdot\text{OOF}$ than O_2F_2 .

3.3.3 Dioxygenyl(II) Complex Fluoride Salts

The synthesis of $\text{O}_2^+ \text{PtF}_6^-$, the first known example of a dioxygenyl salt, was reported in 1962 by Bartlett and Lohmann. Since then numerous other O_2^+ salts have been synthesized and studied. These salts are potential oxidizers for high energy solid propellants.

Dioxygen fluoronium and dioxygenyl saline compounds, such as $[\text{O}_2][\text{BF}_4]$ or $[\text{O}_2][\text{PF}_6]$ were obtained from O_2F_2 with Lewis acids [198, 199] and from O_2F_2 with BF_3 or PF_5 [200]. O_2PF_6 is unstable at room temperature, but O_2AsF_6 and O_2SbF_6 are stable under inert gas up to 373 K (100 °C).

Irradiation of mixtures of liquid oxygen and fluorine at 77 K appeared to result in the formation of appreciable yields of ozone difluoride and oxygen difluoride via a short chain reaction [201]. Treatment of the irradiated mixtures with boron trifluoride at 77 K led to the recovery of a white powder, reasonably stable at room temperature in dry air, in amounts from 20 to 250 mg. The powder was identified as $[\text{O}_2^+][\text{BF}_4^-]$ from elemental analysis, paramagnetic resonance and XRD.

The structure of solid $[\text{O}_2][\text{BF}_4]$ and the kinetics of decomposition of this salts were examined using ^{18}F tracer methods and the presence of OOF free radicals during $[\text{O}_2][\text{BF}_4]$ decomposition was theorized [202].

The reactivity of O_2F_2 with other fluorides such as ClF_3 , SbF_5 , BF_3 , MoF_6 , WF_6 , and SiF_4 has been studied in the search for Lewis adducts or ionic salt formation [203].

Both oxygen difluoride and a mixture of oxygen and fluorine react with AsF_5 or SbF_5 to give dioxygenyl salts under moderate pressures and elevated temperatures [204]. Initial attempts to prepare dioxygenyl salts from BF_3 , PF_5 , SiF_4 , BrF_3 , BrF_5 , or IF_5 with OF_2 were unsuccessful. Instead, dioxygenyl tetrafluoroborate was prepared by reaction of O_2F_2 or O_4F_2 with BF_3 at low temperatures [205]. Isotopic tracer studies of the reaction indicated that the compound is dioxygenyl tetrafluoroborate, $[\text{O}_2^+][\text{BF}_4^-]$ rather than a coordination compound, $\text{FO}_2 \rightarrow \text{BF}_3$. It was suggested that O_2F is the intermediate in both the preparation and decomposition of $[\text{O}_2^+][\text{BF}_4^-]$.

Electron spin resonance spectra of polycrystalline O_2BF_4 , O_2AsF_6 , O_2SbF_6 , and $\text{O}_2\text{Sb}_2\text{F}_{11}$ were recorded over the temperature range from 83 to 293 K (–190 to +20 °C) at 9.35 GHz and indicated that the ions are in sites of orthorhombic or lower symmetry [206].

A deep violet compound was obtained by the reaction of O_2F_2 with ClF at 140–119 K (–133 to –154 °C) [207]. This compound was a strong oxidizer and was stable at 195 K (–78 °C). It was soluble in anhydrous HF at 195 K (–78 °C) and was not an electrolyte. The violet and the blue compound exhibited an infrared absorption at 1535 and 1527 cm^{-1} , respectively, and were interpreted in terms of the peroxides F_2ClOOF and $\text{F}_2\text{ClOOCIF}_2$, respectively.

Dioxygenyl salts containing doubly charged mononuclear counterions such as $(\text{O}_2^+)_2[\text{MF}_6]^{2-}$ ($\text{M} = \text{Ni}, \text{Mn}$) are marginally stable up to about 263 K (10 °C) and are characterized by an O–O stretching frequency of about 1805 cm^{-1} [208].

It was attempted to react sodium azide or hydrazinium azide with various dioxygenyl salts to make a new oxidizer, but under no circumstances could the formation of dioxygenyl azide, O_2N_3 , be observed [209, 210]. Another oxygen-fluorine cation that forms stable salts is the trifluorooxonium cation OF_3^+ [211].

4 Trioxygen Difluoride and Tetraoxygen Difluoride

The synthesis of trioxygen difluoride, O_3F_2 , “ozone fluoride”, CAS RN [16829-28-0] from the elements was first reported by Japanese scientists in 1938 [212, 213] but the news was received with skepticism by others. They had reported that under illumination with ultraviolet light the reactions

and

take place to some extent. Two compounds, $\text{O}_2\text{F}_2(\text{solid})$ and $\text{O}_3\text{F}_2(\text{solid})$, were also formed by silent discharges in the mixture of $\text{O}_2(\text{liq}) + \text{F}_2(\text{gas})$. It was not until 20 years later that the reaction was reproduced and the existence of O_3F_2 confirmed by work at the Research Institute of Temple University in Philadelphia, PA. Since then this compound has received attention as a potential hypergolic ignition aid in rocket propellants [214]. A trace (0.05 mass-%) of ozone fluoride in LOX makes the oxidizer hypergolic with many fuels (hydrocarbons, amines, gaseous hydrogen) and results in more stable combustion in a rocket engine.

Trioxygen difluoride is thermally unstable and even less stable than dioxygen difluoride, but under the anticipated conditions of usage it would always be dissolved in liquid oxygen and kept at cryogenic temperatures all the time.

The conditions under which dioxygen difluoride, trioxxygen difluoride, and tetraoxygen difluoride form from fluorine and oxygen are all very similar and the only difference in the operating conditions is the different molar ratio of the reactants [215]. The discussion of the preparation, physical and chemical properties of tetraoxygen difluoride has been combined in this chapter with those for trioxxygen difluoride.

4.1 Preparation of Trioxxygen Difluoride and Tetraoxygen Difluoride

Trioxxygen difluoride is formed if one passes a mixture of gaseous oxygen and fluorine (molar ratio 3 : 2) at low pressure (1.6 kPa = 12 mm Hg) and low temperatures (83–90 K = –190 to –183 °C) through a glow discharge [214, 216, 217]. The apparatus used by the early investigators is illustrated in Figure 5.

Figure 5: Apparatus for synthesis of trioxxygen difluoride (reproduced and modified after [216])

The compound condenses on the walls of the discharge vessel as a red, viscous liquid that can be freed from contaminating dissolved oxygen, fluorine or oxygen difluoride by evacuation. In contradistinction to O_2F_2 , the O_3F_2 is still a liquid at the temperature of liquid oxygen (90 K = –183 °C) and one can tell the difference by observing the condensate at this temperature. As long as all necessary precautions are observed, O_3F_2 can even be distilled (sublimed) in a high vacuum at 96–114 K and 0.1–1.5 mm Hg. One must be careful not to allow the temperature to rise above 115 K as O_3F_2 decomposes in an exothermic reaction, first to O_2F_2 and oxygen, and then to the elements.

If the temperature increases beyond 200 K, then O_2F_2 decomposes into its elements. The decomposition reaction is not explosive between 90 and 115 K. Liquid O_3F_2 cannot be made to detonate by an electric spark or a detonator [218]. In this respect it is less dangerous than liquid ozone.

By making slight changes in the operating conditions of the glow discharge synthesis of O_3F_2 (lower temperature 60–77 K instead of 90 K, and lower current and voltage i.e. 4.5–4.8 mA at 840–1280 V instead of 20–30 mA at 2000–3000 V), Grosse and co-workers succeeded in synthesizing another polyoxygen-fluorine compound, tetraoxygen difluoride O_4F_2 , which they called “oxozone fluoride”. O_4F_2 can be produced by an electrical discharge at low temperatures and pressures by using a mixture of 2 mols O_2 to 1 mol F_2 by cooling more effectively and to lower temperatures, i.e., 60–77 K (instead of 90 K) [215]. Improved O_4F_2 yields were obtained when the apparatus was made of copper instead of Pyrex because the unstable product could be quenched faster [219]. Tetraoxygen difluoride is a solid at 77 K and sometime condenses on the cold wall between the electrodes in the form of red-brown crystal bundles. At 90 K its vapor pressure is much less than 1 mm Hg. At 90 K it can be stored for several hours and no decomposition takes place (based on pressure rise measurements). At 77 K O_4F_2 is a reddish brown solid, depositing on the glass walls of the discharge vessel between the electrodes. O_4F_2 differs in color from O_3F_2 , and sometimes forms clusters of long needle-like brown crystals. It is a liquid and stable at least for a couple of hours at 90 K, since no noticeable rise in pressure occurs. Between 90 and 110 K, O_4F_2 decomposes slowly into O_2 and O_3F_2 and the latter at 110 K to O_2 and O_2F_2 . Since O_2F_2 , in turn forms $O_2 + F_2$ at about 200 K, the whole O_4F_2 is decomposed entirely into O_2 and F_2 gas. The chemical composition of O_4F_2 was established both by synthesis and analysis. One had to make sure that the condensate did not contain O_3 . The condensate was extracted with LOX in which ozone is quite soluble and the LOX was analyzed for O_3 , but none was found. It has been proven that O_4F_2 is not an adduct of O_3F_2 with oxygen or ozone, but it is a chemical compound in its own right. Careful analysis showed the F:O ratio to be $1.98 \pm 0.005:1$ (theoretical 2:1). Tetraoxygen difluoride is somewhat soluble in liquid oxygen at 77 K and forms a faintly brown solution. No additional properties could be obtained so far. Other work indicated that there may be even higher oxygen-fluorine compounds such as O_5F_2 and O_6F_2 (see Section 5).

Instead of starting with a mixture of elemental oxygen and fluorine, the polyoxygen difluorides can also be made starting with mixtures of oxygen difluoride and fluorine [220].

A continuous process of preparing solutions of O_3F_2 in LOX by bubbling gaseous fluorine through LOX in a quartz Dewar while illuminating it with UV light is described in a patent [221].

The effects of electrode geometry and operating conditions on the O_3F_2 yield were studied [222].

4.2 Physical Properties of Trioxygen Difluoride

Trioxygen difluoride is a solid at the temperature of liquid nitrogen (77 K), a liquid at the temperature of liquid oxygen (90 K) and decomposes at 120 K. Because the compound is difficult to obtain in the pure state and thermally unstable, only very little work has been done in characterizing its physical and thermodynamic properties. The melting point of O_4F_2 was found to be 82 ± 2 K. The extrapolated normal boiling point of O_4F_2 is 194 K. The compound decomposes completely below this temperature. The density of liquid O_3F_2 can be calculated from the following linear equation which is a curve fit of the data shown in Figure 6.

$$\rho = 2.357 - 0.00676T$$

where ρ is the density in g/cm^3 and T is the temperature in kelvin.

Figure 6: Density of trioxygen difluoride (chart created by Schmidt 2016, based on data from [216]). Solid circles: data points, solid line: curve-fit linear equation

The vapor pressure of O_3F_2 can be calculated from the following logarithmic equation, which is a curve fit of the data shown in Figure 7.

$$\log p_v = 4.7277 - 520.7/T$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin.

Figure 7: Vapor pressure of trioxxygen difluoride (chart created by Schmidt 2016, based on data from [216]). Solid circles: data points, solid line: curve-fit equation

4.2.1 Thermodynamic Properties of Trioxxygen Difluoride

The enthalpy of formation of O_3F_2 was calculated from the heat of reaction of the following two decomposition reactions:

The standard enthalpy of formation ΔH_f^{298} of $\text{O}_3\text{F}_2(\text{g})$ is $+26.1 \pm 3.1 \text{ kJ/mol} = +6.24 \pm 0.75 \text{ kcal/mol}$ [223]. Trioxxygen difluoride is an endothermic compound and its autodecomposition is an exothermic reaction and measured in a calorimeter to determine its heat of formation. In the same apparatus the standard enthalpy of formation ΔH_f^{298} of gaseous dioxygen difluoride was measured and it was found to be $+19.8 \pm 1.2 \text{ kJ/mol}$ ($+4.73 \pm 0.3 \text{ kcal/mol}$).

4.2.2 Optical Properties of Trioxxygen Difluoride

Trioxxygen difluoride is soluble in perhalogenated solvents. A mixture of trifluorochloromethane and difluorodichloromethane was used as a solvent to measure the absorption spectrum of O_3F_2 in the visible range at 77 K [224]. Trioxxygen difluoride absorbs at 380–430 nm (molar coefficient of extinction = $\epsilon = 17.0 \pm 0.5 \text{ cm}^{-1} \text{ mol}^{-1}$) (Figure 8). This maximum absorption is somewhat shifted toward the long wavelength end of the spectrum compared to that of dioxygen difluoride O_2F_2 ($\epsilon = 14.0 \text{ cm}^{-1} \text{ mol}^{-1}$ at 360 nm).

Figure 8: Absorption spectra of trioxygen difluoride, dioxygen difluoride and ozone solutions in Freon 12/13 mixture at 77 K (republished and modified from [224], with permission granted by © 1961 American Institute of Physics; permission conveyed through Copyright Clearance Center, Inc.)

The maximum absorption for liquid O_3F_2 occurred in the region of 380–430 nm, the molar extinction coefficient being $17.0 \pm 0.5 L cm^{-1} mol^{-1}$. Liquid O_2F_2 has its maximum at 360 nm ($14.0 L cm^{-1} mol^{-1}$). Neither liquid O_3F_2 nor liquid O_2F_2 has any absorption at the wavelength that ozone has at its maximum ($3.1 L cm^{-1} mol^{-1}$ at 600 nm). The effect of temperature on the absorption of liquid O_2F_2 in the Freon mixture was studied. It was observed that the higher the temperature, the greater the absorption. Its molar extinction coefficient at 360 nm was 14.10 at 77 K, 15.27 at 140 K, and $15.65 L cm^{-1} mol^{-1}$ at 175 K. This agreed nicely with the color change of O_2F_2 with temperature (cherry-red liquid at 175 K and yellow-orange solid at 77 K).

During the study of EPR spectra of O_2F_2 and O_3F_2 , a free radical giving an asymmetric spectrum was discovered [183]. In continuation of these studies, when the EPR spectrum of undiluted solid O_4F_2 was studied at 77 K, a single broad band signal was obtained having a peak-to-peak line width value of 52 ± 1 gauss and a g value of 2.003 [225]; however, a different EPR spectrum was obtained for dilute samples (~ 0.2 mol %) in CF_4 prepared at 90 K and studied at 77 K. That spectrum consisted of a strong,

sharp doublet and not completely resolved shoulders on either side of the doublet. The hyperfine splitting of the doublet was 14 ± 1 gauss and the g value was 2.005. These observations indicated that there were two different species in the sample, most likely $\bullet\text{OOF}$ and its dimer O_4F_2 .

Tetraoxxygen difluoride (O_4F_2), a red unstable solid with a melting point of 82 K, can be prepared by electrical discharge in an oxygen/fluorine gas mixture ($\text{O}_2:\text{F}_2 = 2:1$) in a Pyrex vessel cooled to 77 K. Because of its instability, information about its structure is limited. ESR and NMR data in solution showed that O_4F_2 is in equilibrium with the radical $\bullet\text{OOF}$. Infrared spectra were consistent with $2\text{O}_2\text{F} = \text{O}_4\text{F}_2$, the spectrum of O_4F_2 being very little different from $\bullet\text{OOF}$. Raman spectra for O_4F_2 were obtained by photolyzing a low-temperature solution of oxygen difluoride (OF_2) in liquid oxygen at about 90 K [226]. The solution of OF_2 in O_2 (approx. 3:1 by volume) was prepared in a simple quartz still. After photolysis with a Pyrex-filtered mercury arc ($\lambda > 320 \text{ nm}$) for some 15 min the solution was deep orange in color and the Raman spectrum was obtained. The closeness of the frequencies for $\nu(\text{O}-\text{O}-\text{F})$ and $\nu(\text{O}-\text{F})$ in matrix and solution suggested that the perturbing influence of the matrix or solution on the vibrational potential function was very small. The position of the $\text{O}-\text{O}$ stretching frequencies suggested that the species produced in solution was O_4F_2 and not $\bullet\text{O}_2\text{F}$. It was noted that the degree of interaction between two $\bullet\text{O}_2\text{F}$ radicals shifted the $\text{O}-\text{O}$ stretch only by 2.5 cm^{-1} and the other vibrations not at all. There is strong evidence that the O_4F_2 molecule is bonded through the oxygens in some manner:

The ESR spectra of oxygen fluoride radicals have been studied extensively, and spectra with varied structures have been assigned to these radicals, with the exception of the well-characterized doublet spectrum for $\bullet\text{O}_2\text{F}$ radicals (splitting 13–16 oersted, g 2.0046–2.0033), and also the anisotropic spectrum, which has been analyzed in detail [227]. The assignment of the other types of ESR spectra to $\bullet\text{O}_2\text{F}$ radicals was extremely arbitrary. At the same time, certain specific features of $\bullet\text{O}_2\text{F}$ radicals required sufficiently reliable identification, since ESR data have been used to reach important conclusions regarding the nature of a number of fluorine-oxygen compounds like O_3F_2 or O_4F_2 . Unlike familiar unstable free radicals, the stabilization of which is achieved by isolating them from each other in a rigid matrix, $\bullet\text{O}_2\text{F}$ radicals are stable both in the form of the individual substance, solid at 77 K, and in solvents that are inert with

respect to $\cdot\text{O}_2\text{F}$ (O_2F_2 , OF_2 , O_2 , CF_4 , etc.). $\cdot\text{O}_2\text{F}$ radicals are sensitive to light in the visible and ultraviolet ranges, and disappear at an appreciable rate at temperatures above 90 K. Since $\cdot\text{O}_2\text{F}$ radicals are sensitive to light with <600 nm, which brings about their transformation, all the operations involving them must be carried out under dark conditions.

4.2.3 Molecular Structure of Trioxygen Difluoride

Because all the oxygen fluorides with more than one oxygen atom at the center are very unstable, it is difficult to determine physical properties (spectra) that would help to determine the structure of these molecules. In many cases, computational chemistry with *ab initio* or DFT methods comes to the aid with predictions on how the electron clouds will hold the atoms together in a labile fashion.

Surface tension, viscosity, dielectric constant, paramagnetic susceptibility, specific susceptibility, molar magnetic moment, electron paramagnetic resonance, nuclear magnetic resonance and infrared spectra of O_3F_2 were measured to determine the molecular structure of trioxygen difluoride [228]. The structure of O_3F_2 could not be clearly defined. There was evidence to support the presence of $\cdot\text{O}_2\text{F}$ and $\cdot\text{OF}$ radicals. The possibility that O_3F_2 is a trimer, at least in the liquid state, could not be ruled out. O_3F_2 is not a compound of ozone. A linear molecular configuration is not possible.

The molecular structure of O_3F_2 has been the subject of heated discussion. It is difficult to analyze the material because it often starts to decompose before a decent spectrum can be obtained.

Cryogenic mass spectrometry led some to conclude that “ O_3F_2 ” consists of loosely bonded $\cdot\text{O}_2\text{F}$ and $\cdot\text{OF}$ radicals [229]. There were no m/e signals attributable to O_2F_2 , O_3F_2 or O_4F_2 , but peaks attributable to OF^+ , F_2O^+ , O_2^+ , O_2F^+ , and F_2^+ . It was concluded that “ O_3F_2 ” is basically an $\cdot\text{O}_2\text{F}$ and an $\cdot\text{OF}$ radical loosely bonded together and that it undergoes thermal decomposition to $\cdot\text{O}_2\text{F}$ and $\cdot\text{OF}$ via the reversible reaction shown in Eq. 2. These conclusions were based mainly on the fact that OF^+ and F_2O^+ were observed in the mass spectrometry studies.

↗ fast

↘

Another far-fetched theory, based on the ^{19}F NMR spectrum of “ O_3F_2 ” postulated that “ O_3F_2 ” consists of O_2F_2 and interstitial oxygen [85, 86].

Finally, work on both ^{19}F and ^{17}O NMR spectroscopy of “ O_3F_2 ” [88, 230–232] led investigators to conclude that the system is best explained as

It was also determined that under ordinary conditions the oxygen atom of OF_2 does not exchange with those of either O_2F_2 or so-called O_3F_2 . The reaction of “ O_3F_2 ” with BF_3

without the release of oxygen also seemed to support a “ O_3F_2 ” consisting of a mixture of O_2F_2 and $(\text{OOF})_2$. All of the evidence obtained supports the conclusion that “ O_3F_2 ” is actually a mixture of O_2F_2 and $(\text{OOF})_2$.

Equilibrium structures of FOOOF in comparison to $\cdot\text{OOF}$, FOOF, and OOF_2 were calculated using a density functional theory (DFT) method and compared with those generated using the *ab initio* calculations and experimental data [180]. The structures of oxygen-fluoride molecules that are known to be problematic for computation were studied using DFT methods. The structures were compared with those generated using the *ab initio* calculations and, when possible, some experimental data. The suitability of the DFT methods for the theoretical study of these molecules is still under discussion.

Coupled-cluster calculations to study the FOOOF isomer of O_3F_2 showed two local minima of similar energy, conformers of C_2 and C_s symmetry [233]. Structures, harmonic vibrational frequencies and standard enthalpies and free energies of formation were calculated. The calculated bond lengths of O_3F_2 were more characteristic of those in OF_2 and a normal peroxide than the unusual bond lengths in O_2F_2 . Both conformers had equal F—O and O—O bond lengths, contrary to suggestions by others of an unsymmetrical structure. The calculated ΔH_f° and ΔG_f° were +110 and +173 kJ/mol, respectively. O_3F_2 was calculated to be stable to decomposition to either $\text{FO} + \text{FOO}$ or $\text{F}_2 + \text{O}_3$, but unstable to decomposition to its elements, to $\text{O}_2\text{F}_2 + \frac{1}{2}\text{O}_2$, and to $\text{OF}_2 + \text{O}_2$.

4.2.4 Magnetic Properties of Trioxygen Difluoride

The ^{19}F NMR spectra of liquid F_2 , OF_2 , O_2F_2 , and O_3F_2 were measured and compared [86]. The results were already discussed in the OF_2 NMR chapter and the O_3F_2 molecular structure chapter. In discussing the molecular structure of O_3F_2 , it was suggested that O_3F_2 is a 1:1 adduct of O_2F_2 and O_4F_2 or an adduct of $2\text{O}_2\text{F}_2$ and O_2 . See also reference [88].

4.2.5 Solubility of Trioxygen Difluoride and Tetraoxygen Difluoride

Trioxygen difluoride is nearly insoluble in liquid fluorine, liquid nitrogen or liquid oxygen at 77 K. At 90 K its solubility in liquid oxygen is very small (0.1 mass-%) and it forms a pale yellow liquid. The solubility of O_3F_2 in LOX is illustrated in Figure 9.

Figure 9: Solubility of trioxygen difluoride in liquid oxygen (based on data from [216])

Trioxygen difluoride is miscible with dioxygen difluoride in all proportions. Perfluorinated or perhalogenated organic solvents (e.g., Cl_2CF_2 or ClCF_3 = halocarbon 12 or 13) can be used to study properties of O_3F_2 in solutions.

Solid O_4F_2 is practically insoluble (less than 0.01 mol %) in liquid nitrogen at 77 K, and in liquid argon at 85 K. In liquid oxygen at 77 K the solubility of O_4F_2 is about 0.05 mol %. Carbon tetrafluoride (Freon-14) dissolves appreciable amounts of O_4F_2 at 90 K (melting point of CF_4 = 89.2 K). The solution containing 1 mol % of O_4F_2 is reddish brown [219].

4.3 Chemical Properties of Trioxygen Difluoride

4.3.1 Decomposition of Trioxygen Difluoride and Tetraoxygen Difluoride

Trioxygen difluoride is thermally unstable. Even at the temperature of liquid oxygen, at 90 K, the rate of decomposition is measurable and amounts to 4%/day. The half-life time at the temperature of liquid nitrogen, at 77 K, is estimated to be 2 years. If one plots the logarithm of the rate of decomposition versus the reciprocal absolute temperature, one obtains a straight line indicating that this is a first-order reaction. From the slope of the line one can calculate the energy of activation of the decomposition reaction ($15.5 \text{ kJ/mol} = 3.7 \text{ kcal/mol}$).

Tetraoxygen difluoride decomposes at 90 K with about a 16-day half-life time to trioxygen difluoride and oxygen. Trioxygen difluoride decomposes in turn, at 90–115 K to O_2F_2 and finally to O_2 and F_2 . Pure O_4F_2 , or its solidified solutions containing about 1 mol % of O_4F_2 in CF_4 has been kept at liquid nitrogen temperature for weeks without noticeable decomposition. O_4F_2 explodes on fast warming.

4.3.2 Storability of Trioxygen Difluoride and Trioxygen Difluoride/ Liquid Oxygen Solutions

The storage life of O_3F_2 solutions in LOX at 90 K was not expected to exceed 1 month. In the 1960s, Air Reduction Co. installed a 25-gallon pilot plant for production of LOX/ O_3F_2 (TOFLOX) with 0.05–0.10% O_3F_2 in LOX in Huntsville, AL, but it is not known if it actually has produced sizable amounts of TOFLOX [234].

4.3.3 Reactions of Trioxygen Difluoride and Tetraoxygen Difluoride

Trioxygen difluoride is a very strong oxidizer and it reacts with all hydrogen-containing substances vigorously with ignition. The reaction with liquid methane, solid hydrazine or solid ammonia at 90 K is so energetic that the glass test tubes used for the reaction are fragmented to small pieces.

Trioxygen difluoride reacts with elemental sulfur, bromine, iodine, red phosphorus, and charcoal in flame reactions, sometimes explosively. A mixture of trioxygen difluoride and ethanol did not react at 90 K but exploded when thawed. The enormous reactivity of trioxygen difluoride is maintained after the compound is dissolved in liquid oxygen. This mixture reacts hypergolically with most rocket fuels [194].

Reactions of O_2F_2 and O_4F_2 with nitrogen oxides produced inconclusive results. Some evidence for NO_2OOF was obtained, but it could not be identified before it decomposed to O_2 and NO_2F [202].

4.3.3.1 Hypergolic Ignition Tests with Trioxygen Difluoride

This chapter actually belongs in a future volume on hypergolic bipropellant combinations, but we summarize the ignition characteristics of O_3F_2 and $\text{O}_3\text{F}_2/\text{LOX}$ solutions

here to better characterize this chemical and to explain why we devoted that much space to it in this chapter.

The first tests of the hypergolization of LOX by addition of O_3F_2 were conducted at Temple University [235, 236]. A dilute solution (0.05%) of O_3F_2 in LOX was used as an oxidizer in an ignition test apparatus and proved to be hypergolic with gaseous H_2 , unsymmetrical dimethylhydrazine (UDMH), UDMH-diethylenetriamine (UDMH-DETA), EtOH, C_3H_8 , *n*-hexane, jet propellant 4 (JP-4) and mixtures of JP-4 and UDMH. Compatibility tests (by simple contact) showed that dilute O_3F_2 /LOX solutions do not react hypergolically with most materials of construction commonly used in LOX systems. Similar tests with emphasis on ignition of hydrogen were conducted at Stanford Research Institute, Menlo Park, CA [237, 238].

4.4 Handling and Safety Properties of Trioxxygen Difluoride

Because pure trioxxygen difluoride cannot be used as a rocket propellant, the concern about safe handling of this energetic material deals mostly with the handling during its manufacture in the pure state and later, in the form of solutions in other oxidizers, predominantly LOX. The lack of thermal stability of trioxxygen difluoride makes it necessary to store it at very low temperatures, typically at the temperature of liquid nitrogen. One will want to make sure that there is always sufficient cryogenic coolant on hand and that contact of the product with organic, combustible substances is avoided. Toxicity concerns are the same as those when dealing with fluorine (liquid or gas) since fluorine is one of the decomposition products once the trioxxygen difluoride starts decomposing. Adding trioxxygen difluoride to liquid oxygen results in stricter safety precautions required for the solution than one is used to for LOX. The LOX/ O_3F_2 tank will be designed with a cooling jacket that holds a supply of liquid nitrogen. If one stores pure LOX, it does not matter how much of the cryogenic oxidizer evaporates, the remaining oxygen will still be pure enough for the intended use. Not so with LOX/ O_3F_2 solutions: if more than 50% of the oxygen is allowed to evaporate, the solubility limit of O_3F_2 in LOX will be exceeded and pure O_3F_2 segregates on the bottom of the tank. Transferring LOX/ O_3F_2 from one tank to another requires additional safety precautions. Unlike LOX transfer where the lines can be allowed to cool by evaporating some LOX and tolerating evaporation losses, for the transfer of LOX/ O_3F_2 the lines must be precooled with LOX from a separate supply or must be externally cooled.

If LOX/ O_3F_2 solutions are stored for a long time, the O_3F_2 content must be examined from time to time and, if necessary, fresh O_3F_2 must be added to maintain the desired O_3F_2 level and its hypergolic ignition capability. Accidental spills of LOX/ O_3F_2 solutions constitute a more significant hazard than LOX spills because the probability of accidental ignition of structural materials in the vicinity of the spill is so much higher. Rocket propellant test personnel are used to prevent air intrusion into LOX to prevent ice formation and clogging of filters and orifices, but for LOX/ O_3F_2 solutions

moisture must be excluded very carefully for an additional reason: O_3F_2 will hydrolyze and lose its hypergolic ignition capability and hydrogen fluoride, one of the hydrolysis products, will cause nasty corrosion problems.

4.5 Materials Compatibility with Trioxxygen Difluoride

The dry, water-free, cryogenic LOX/ O_3F_2 solution (typically containing 0.05% O_3F_2) can be stored in CRES-303, CRES-316, CRES-321, CRES-347, aluminum, copper, brass, or titanium alloy 120-VCA.

Allpax-500, Teflon, and Duroid-3400 have been used as gasket materials and Molycote-Z and Oxylube-702 have been used as lubricants. For higher concentrations (0.11% O_3F_2 in LOX) the following materials of construction are no longer resistant: Kel-F, polyethylene, Kel-F Oil 464, Halocarbon 11,14 Oil or AR-1 F-LOX-lube, but CRES-303 is acceptable even for the higher concentrations [214].

The compatibility of metallic and organic structural materials with 0.05% solution of O_3F_2 in LOX was investigated under static and flow conditions [118, 120].

4.6 Detonability of Trioxxygen Difluoride

In a 1-in. diameter $\times$ 8 in. length steel pipe initiated with two 1 in. $\times$ 1 5/8 in. diameter tetryl pellets as the booster charges, a charge of liquid trioxxygen difluoride was not detonable [239, 240].

5 Other Oxygen Fluorides

Speculation had it that oxygen as the central atom might be pushed to higher, hypervalent states of oxidation and that higher oxygen fluorides like OF_5 or OF_6 might be possible. Two new oxygen fluorides, O_5F_2 and O_6F_2 , were discovered and methods of preparation and some of the properties of these new oxygen fluorides were described [191, 192]. Synthesis of polyoxxygen difluorides by electrical discharge in the liquid phase or ultraviolet irradiation was accomplished. Thermal stability, sensitivity, solubility, and the EPR spectrum for O_5F_2 were determined.

An *ab initio* study of the electronic structure of OF_6 has been undertaken [241]. Optimized geometries were calculated at the self-consistent field (SCF) and Moeller-Plesset (MP2) levels of theory using several basis sets. Vibrational analyses indicated that OF_6 has stability in $[O_h]$ symmetry at both the SCF and MP2 level. The calculations suggested a stability competition between the covalent $[O_h]$ structure and the $[\text{C}_{4v}]$ OF_5^+F^- ion-pair structure.

Ozone and Ozone/Oxygen Mixtures

1 Introduction

Ozone, O₃, also known as 1λ,1,3λ,1-trioxidane, μ-oxidodioxygen, trioxygen, triatomic oxygen, CAS RN [10028-15-6], is an allotrope of dioxygen consisting of three instead of only two oxygen atoms. Ozone, O₃ (in the liquid form frequently abbreviated as LOZ = **L**iquid **O**Zone), is a more energetic form of oxygen, and its safe use as a rocket propellant would give a higher specific impulse than liquid oxygen with all fuels. The various reactions that will be discussed in this chapter convert one form of oxygen into an other:

Ozone is an even more powerful oxidizing agent than dioxygen and has been experimentally tested as a rocket propellant, but it has never been demonstrated to be safe or practical to use. To our knowledge, it has never actually flown in a rocket. Compared to another high-energy oxidizer, fluorine, ozone has the advantage that exhaust products from a bipropellant rocket engine running on ozone are non-toxic. Another advantage is that the starting raw material, dioxygen, is in abundant supply. A significant disadvantage is that liquid ozone is very shock sensitive and unstable, decaying to dioxygen through the exothermic reaction

This reaction proceeds more rapidly with increasing temperature and decreasing pressure but is very slow at cryogenic storage temperatures.

In addition to very active research into ozone as an energetic chemical and potential rocket propellant, much effort has been devoted to looking for polyoxygens with four or more oxygen atoms joined in one molecule. If such compounds could be made and stabilized, they would make powerful rocket propellants. Thus, we present a detailed account of ozone chemistry here because it would be the jumping board from which to start in the search for even more energetic all-oxygen oxidizers.

1.1 Ozone History and Literature Summaries

An excellent summary of the history of the discovery and characterization of ozone is given in [1]. Ozone has been known for a long time, and many published books and monographs have dealt with the chemistry and general aspects of this chemical. Some of these titles are now only of historical interest. Judging by the number of books published, it seems that the interest in ozone as a chemical culminated in the year 1916: [2–4]. Then, following a quiet period of four decades, ozone chemistry experienced a resurgence when NACA and other rocket propulsion organizations began to look at ozone as a rocket propellant and a series of good summaries became available [5–10]. Among those, the two-volume bibliography by Thorp is a valuable source of information.

When the concern about the toxicity of chloroform and other halogenated organics in drinking water caused water treatment facility operators to look at other means of disinfecting drinking water, ozone stepped up as a clean, residue-free disinfectant to replace chlorine. It is quite possible that today's widespread use of ozone as a water treatment chemical has benefited from the extensive research done in the 1950s with government funding when ozone was slated for use as a rocket propellant.

Then, after interest in ozone as a rocket propellant waned, it was the atmospheric research enabled by high-altitude sounding rockets and satellites in the 1960s and 1970s that identified the deleterious effect of halocarbons on the protective ozone layer on Earth and on the formation of an so-called ozone hole over the poles that spurred an increase, by several orders of magnitude, in the annual number of publications on the ozone, mostly on atmospheric chemistry. There exists a dual concern about ozone: the unwanted abundance of ozone in smog at the bottom of the polluted atmosphere where we live and breathe and a shortage of ozone at the top of the atmosphere, where it is supposed to absorb skin- and vegetation-damaging UV rays from the Sun and protect us from sunburns. There is even a scientific society dedicated exclusively to the study of ozone for industrial uses in water treatment and its significance for life on Earth. Since 1979, the society has even been publishing a bimonthly journal: *Ozone: The Journal of the International Ozone Association* [11].

The first preparation of pure ozone and determination of several of its physical properties was done by E. H. Riesenfeld at the University of Berlin during the period 1922–1926 [12, 13]. Ever since the pioneering work of Riesenfeld there has been no lack of attempts to liquefy ozone and use it as a rocket propellant. These efforts were frustrated by the explosive sensitivity and explosive power of liquid ozone, which has been the cause of frequent accidents, which led other investigators to the conclusion that the utilization of pure ozone as a rocket propellant would be impossible.

Karrer and Wulf also reported the preparation of pure liquid ozone and determination of its molecular mass in 1922 but were frustrated by frequent explosions at various stages of their experiments [14].

Some of the early work on ozone with the intent of using it as a rocket propellant was conducted by Schumacher in cooperation with rocket pioneer Eugen Sänger [15–17].

Following the end of World War II, efforts aimed at the production of ozone as a rocket propellant continued undiminished in the USA and in what was then the USSR. In the United States, Armour Research Foundation, in conjunction with Linde Air Products and Air Reduction Co. (Murray Hills, NJ), was one of the leading ozone research organizations at that time [18]. This group succeeded in 1955 in preparing extremely pure ozone and identifying some of the causes of explosive sensitivity of samples prepared by earlier investigators [19].

If not for its hazardous properties (explosivity and toxicity), liquid ozone would make a good oxidizer in combination with fuels such as liquid hydrogen or hydrocarbons. The advantage over liquid fluorine would be not only that some ozone combinations give higher specific impulse, but also that the exhaust gases are non-toxic. It was expected that the production of liquid ozone would be less expensive than that of liquid fluorine. Despite this, liquid fluorine appeared to be the leading oxidizer candidate in the 1960s when high-energy propellants were the name of the game, regardless of their toxicity. It was argued that the hazards of liquid fluorine are somewhat more predictable, whereas the handling of liquid ozone sometimes resulted in unexpected, unpredictable, and hard-to-explain explosions.

1.2 Advantages and Disadvantages of Ozone as a Rocket Propellant

In a comparison of the advantages and disadvantages of fluorine versus ozone conducted in 1959, it was argued (but without substantiation of claims by hard numbers) that neither of the two oxidizers justifies the high expense of research and development, because non-chemical propulsion systems would soon replace all high-energy chemical rocket propellants in satellites and space probes [20]. This pessimistic view was not immediately confirmed, at least not for the next 10 years while the development of the NOMAD upper stage using liquid fluorine as the oxidizer continued until it also was abandoned as impractical.

With regard to future applications of ozone as a rocket propellant, initial developments will, in all likelihood, use not pure ozone but mixtures of liquid ozone with liquid oxygen or liquid fluorine. For this reason, this chapter combines a discussion of the physical and chemical properties of pure ozone by itself with those of its mixtures.

The following historical literature summaries (only second-hand sources of information) may be useful as an introduction to the use of ozone as a rocket propellant and its hazards: [21–23].

Today the main applications of ozone are in drinking water purification and sterilization and the treatment of industrial waste waters. It has the advantage that it can destroy infection-bearing bacteria and organic contaminants without forming danger-

ous halocarbons (in particular, chloroform) as happens with treatment using elemental chlorine or hypochlorite.

2 Preparation, Production, and Availability of Ozone

Ozone is produced by a silent discharge (“corona discharge”) in oxygen or air at sea level pressure by an endothermic reaction. The resulting ozone has a positive enthalpy of formation. Good yields are achieved with oxygen flowing past large surface area electrodes connected to alternating-current voltages of 5 to 10 kV.

Dissociation of molecular oxygen:

Depending on the operating conditions, the product gas can contain 3 to 15% ozone. The reaction product can be condensed into a cold trap in liquid nitrogen, and the residual gas can be recycled into the closed-loop apparatus. If one connects several ozonizers in series, the maximum concentration of ozone in the product is limited to a stationary concentration of about 20% because some ozone decomposes back to oxygen under the conditions of its formation in the silent discharge.

Ozone can also be formed by UV illumination of oxygen in analogy to processes in the upper atmosphere of Earth leading to the formation of a protective ozone layer. Regardless of the method of stimulation, electric discharge or UV light, the maximum concentration of ozone in the products of a single-pass ozonizer is limited. There is a dynamic equilibrium that can be shifted only by condensing ozone and removing it from the reaction zone.

If the ozonizer is operated on dry air instead of pure oxygen, the resulting ozone is contaminated by nitrogen oxides, mostly dinitrogen pentoxide, which can also be obtained in separate reactions of nitrogen dioxide with ozone. The percentage conversion of oxygen to ozone in dry air can be higher than in pure oxygen [24, 25]. Traces of moisture, however, reduce the ozone yield substantially. Commercial ozonizers are available in a wide range of models [26].

For all these devices, the ozone yield as a function of electric power consumption is an important evaluation criterion [27]. A group of Russian scientists conducted a systematic evaluation of the fundamental operating parameters of ozonizers to optimize the yield of ozone and published two long series of publications with 12 sequels. The variables studied included the electrode geometry, the space velocity of oxygen feed gas, the admixture of inert diluent gases, the discharge voltage, the discharge current, and the frequency of the alternating current. The results obtained with different reactor designs were normalized by the power : volume ratio of the reactors. The pressure and temperature of the feed gas also have an influence on the ozone yield. These

publications deal with the kinetics of the synthesis of ozone under flow conditions [28], the synthesis of ozone from oxygen-argon mixtures [29], the effect of electrode temperature [30], operation under reduced pressure [31], steady-state conditions [32], ozone formation in oxygen-nitrogen mixtures [33], the power effect of discharge [34], kinetics in a closed-loop ozonizer [35], and combining several ozonizers [36]. Another series of publications dealt with the electrical theory of ozonizers [37–46]. The best ozone yields are achieved if the pressure and flow rate in the ozonizer are carefully controlled [47]. See also [48].

The design criteria for laboratory-scale ozonizers were described in [49] and [50]. Ozonizers can also be operated at high pressures [51]. One must avoid electrode materials that might catalyze the decomposition of ozone [52]. Sometimes it is best to encase electrodes in glass.

The explosive sensitivity of liquid ozone has been blamed on the presence of organic contaminants [19]. The most likely source of contaminants is the oxygen derived from air liquefaction by compression and adiabatic expansion. The compressors used for compressing air must be lubricated, and some parts run very hot. At that temperature, some of the oil is thermally cracked to form lower, more volatile hydrocarbons, including acetylene, which is difficult to separate from liquid oxygen by distillation or freezing and filtering. Liquid oxygen may typically contain up to 3 ppm acetylene at 90 K (–183 °C). Lowering the acetylene concentration to 0.003 ppm did not totally alleviate the explosive problem because sporadic explosions still rendered the ozone product unsafe.

Extremely pure oxygen suitable for ozone production can be obtained by passing the gas over hot copper(II) oxide, which destroys all organic contaminants [53]. Ozone that was prepared from oxygen purified in this manner could be liquefied without problem and was much less sensitive to shock and vibration than previously prepared samples.

To study ozone formation in the solid state, gaseous oxygen was passed through an electrodeless discharge and condensed, either alone or in a matrix of inert gases, at liquid helium temperature [54]. On warming through a temperature range of 13–30 K, the blue solid deposits became more deeply colored. The amount of ozone formed as a function of time was determined. It was concluded that ozone was formed upon condensation by the predominant reactions from atomic oxygen

The experimentally observed conversion to ozone of 58% agreed well with that calculated from a rate law with $k_1/k_2 = 1.3$. The activation energy of these reactions was estimated to be less than 6.3 kJ/mol (1.5 kcal/mol). At one point, atomic oxygen was considered for use as a cryogenic solid rocket propellant. This reaction would essentially limit the useful life of atomic oxygen before it recombines.

Ozone can form by the reaction of fluorine gas with water or during the decomposition of peroxides. Ozone is formed in good yield by reacting O^{2+} salts with water in HF at 195 K ($-78^{\circ}C$). Using isotopically labeled water, ^{17}O - ^{16}O - ^{16}O and ^{18}O - ^{16}O - ^{16}O can be prepared, and other isotopomers could be made starting with $^{17}O^{2+}$ and $^{18}O^{2+}$ precursors [55]. ^{17}O nuclear magnetic resonance (NMR) spectroscopy and IR matrix spectroscopy were used for the detection and a study of the decay of the isotopomers. The ^{17}O or ^{18}O label remained at the terminal position as long as the sample was kept at or below 195 K ($-78^{\circ}C$), but at higher temperatures scrambling of the atoms was observed.

In most cases of rocket applications, one will not want to use pure ozone, but ozone solutions in liquid oxygen. Such solutions can be prepared by bubbling ozonized oxygen through a sample of liquid oxygen that is externally cooled by a bath of liquid air or liquid nitrogen. Liquid oxygen and liquid ozone are not miscible over the entire range of compositions at the temperature of liquid oxygen. Instead, at the temperature of liquid oxygen, there are two phases, a lower one containing 30 mass-% oxygen dissolved in ozone and the upper layer of 30 mass-% ozone dissolved in oxygen. In the hope that all explosive hazards of ozone/oxygen solutions can be brought under control, some companies started with the design of plants for the production of liquid ozone/liquid oxygen (LOZ/LOX) in 1952 [56]. However, none of these projects was brought to fruition.

Some organizations were overly optimistic in believing it would be possible to use liquid ozone as a rocket propellant on a large scale and in making preparations to produce tonnage quantities of the chemical [57]. However, they advised against the preparation and storage of solid ozone.

A simple method for producing (100%) pure ozone in the laboratory is the silent electric discharge technique [58]. The specific production costs of ozone were estimated for a capacity range of 1 to 1000 kg/h ozone for various plant configurations and air or oxygen as feed gas and for air preparation, onsite liquid oxygen delivery, onsite oxygen production, and/or oxygen recycling systems [59].

The γ -irradiation of liquid or solid oxygen is one method for producing ozone [60, 61]. In undiluted oxygen at 77 or 90 K, the G-value was 6 molecule/100 eV absorbed. The presence of nitrogen will cause the formation of unwanted NO_2 .

2.1 Natural Occurrence of Ozone

2.1.1 Natural Occurrence of Ozone on Earth

Ozone in small quantities is formed by several physical and chemical processes. Lightning strikes leave behind the telltale odor of ozone. Ionizing radiation from radioactive isotopes will ozonize the surrounding air. The cabin air of airplanes flying at high altitudes and using ambient air may contain irritating amounts of ozone. Ozone can often be smelled in the vicinity of laser printers or copy machines. Federal and state

regulations limit the allowable concentration of ozone in the air in places of employment (Section 6.1). Ozone is indisputably a minor atmospheric constituent, but it plays a major role in the physico-chemistry of the atmosphere. At the height of the sometimes hyped public concern about the ozone hole and before the legally enforced reduction in halocarbon emissions began to take effect, one of the most absurd proposals to patch the ozone hole was to load several rockets with a payload consisting of tons of liquid ozone (if not as the oxidizer that propelled the rocket) and disperse it in the ozonosphere.

2.1.2 Natural Occurrence of Ozone on Extraterrestrial Planetary Bodies

There has been speculation that some ozone might have formed under the influence of energetic radiation on dioxygen and condensed in a matrix of ice or solid oxygen in cold parts of the Universe, where it might be preserved for a long time.

The detection of ozone on Europa and Callisto was surprising, since the vapor pressure of solid oxygen exceeds the atmospheric pressures of these satellites. Condensed O_2 and O_3 on the surfaces of some icy satellites are thought to originate from the radiolytic decomposition of surface water ice by the impact of energetic magnetospheric ions, but decades of laboratory studies have produced no evidence for ozone from the radiolysis of pure water ice. In trying to reproduce those conditions in a laboratory on Earth, it was found that codeposition during radiation caused the burial of a high concentration of radiolytic O_2 from which ozone was formed [62, 63]. Irradiation was done at 130 K with 100 keV Ar^+ ions. The UV reflectance spectra of the irradiated ice matched those observed on the icy satellites Ganymede and Rhea.

The mass uptake of ambient oxygen in nanoporous ice could be enhanced by irradiation with 193-nm photons, due to conversion of O_2 into H_2O_2 and O_3 , with an efficiency that increased with decreasing temperature [64]. These findings showed a new way to form H_2O_2 and O_3 on icy surfaces in the outer solar system at depths much larger than are accessible by typical ionizing radiation, which has possible astrobiological implications. In the search for *in situ* resource utilization (ISRU) resources, one must be prepared to encounter ozone in addition to the more desirable hoped for discovery of water and oxygen. The question is whether this discovery of ozone should be considered a detriment, making the oxygen unfit for breathing, or a benefit, allowing one to scoop up a more energetic oxidizer propellant for the trip home. The discovery of ozone and/or hydrogen peroxide on the surface of Mars and its icy satellites would make the extraterrestrial existence of life forms as we know them highly unlikely because both are very effective disinfectants.

3 Physical Properties of Ozone

The molecular mass of ozone is 47.9982 g/mol. In the liquid phase, ozone has an indigo-blue color. At temperatures around 90 K (–183 °C), liquid ozone may be kept without noticeable decomposition for long periods. Fast warming to the boiling point or rapid cooling may cause explosions. The liquid ozone must be evaporated or frozen very slowly with appropriate precautions. Liquid ozone has a tendency to supercool instead of crystallizing. Solid ozone has a deep blue-violet color. A layer 0.2 to 0.5 mm is transparent, but solid ozone in a layer 1 mm thick is almost opaque. Solid ozone (at 77.35 K) was compressed to 22.5 atm without any difficulty. Slight impact and slight friction at that temperature did not cause an explosion. Gaseous, liquid, or solid ozone explodes easily if it is exposed to heat, sparks, flames, or shocks. The presence of contaminants enhances its sensitivity.

Quite often physical properties of pure ozone are listed in the same publications that also deal with its mixtures with oxygen. We had to decide whether properties of ozone/oxygen mixtures should be listed immediately following the property of pure ozone or if mixtures should be moved to a separate subsection at the end of the ozone chapter. The decision was made to list the properties of mixtures of ozone and oxygen at the end of each property chapter. A discussion of mixtures of ozone with other oxidizers (fluorine, nitric acid) appears at the end of this chapter.

The density, melting points, and boiling points of ozone are higher than those of oxygen.

Because it is difficult to work with pure ozone, the physical properties of this compound have not yet been determined with the same accuracy as those of oxygen. In particular, physical properties reported in older publications must be treated with a good amount of distrust. Discrepancies were caused by impurities in the ozone and shortcomings inherent in the experimental methods used. In cases of discrepancies, it is difficult to decide which values are correct without repeating the experiments with modern methods.

Good summaries of physical properties of ozone were published at a time when hopes for the future use of ozone as a rocket propellant were still running high [6, 7, 18, 65, 66].

3.1 Freezing Point and Phase Diagrams of Ozone

It is difficult to measure the freezing point of LOZ and LOX/LOZ mixtures because it has a tendency to supercool. Warming frozen ozone to determine the melting point is a hazardous operation. Melting point data for ozone are summarized in Table 1.

In one experiment, ozone was frozen in a bath of liquid/solid nitrogen slush at the triple point of nitrogen, then the liquid nitrogen bath was warmed by slow addition of oxygen at a rate of 0.06°/min ([67]). Melting of solidified ozone was observed to begin

Table 1: Melting point of ozone.

Melting point		Authors	Year	References
K	°C			
80 ± 0.5	-193 ± 0.5	Brown, Berger, and Hersh	1954	[67]
80.7 ± 0.4	-192.5 ± 0.4	Jenkins	1956	[68]

at 79.7 K (-193.4°C), and melting was complete at 80.6 K (-192.5°C). The true melting point of solid ozone is $80 \pm 0.5\text{ K} = -193 \pm 0.5^\circ\text{C}$.

3.1.1 Phase Diagram of Ozone/Oxygen System

Ozone and oxygen are miscible over the entire range of compositions only above a critical mixing temperature, for which various sources give 93.2 K (-179.9°C) or 92.6 K (-180.5°C). Below this temperature the mixtures separate into two phases. The lower phase is an ozone-rich phase. The lower phase, containing 44–65 mol-% ozone, is much more sensitive than the homogeneous solution. Phase separation must be avoided if one wants to use LOX/LOZ mixtures as rocket propellants. Several investigators have been looking for an additive that will prevent phase separation.

The phase diagrams of the binary system liquid and solid ozone and oxygen have been studied extensively [69–71].

Table 2–4, and Figure 1 and 2 give the composition of the ozone-rich phase and the oxygen-rich phase in the two-phase region of ozone/oxygen mixtures.

Table 2: Composition of immiscible O_3/O_2 phases in two-phase region.

Temperature		Composition, mol-% O_3	
K	°C	Oxygen-rich phase	Ozone-rich phase
78	–195	5.3	65
85	–188	10.0	58
88	–185	18.0	48
91	–182	—	44.5
92	–181	24.5	—

Data source: [69]

Curve I in Figure 2 gives the experimental results. Curve II is the “theoretical” curve, assuming Raoult’s law will hold. Curves I and II are quite different. The “experimental” curve I shows a small but distinct maximum at $167.8 \pm 1\text{ K}$ ($-105.3 \pm 1^\circ\text{C}$). At this temperature and a pressure of 760 mm Hg the gas and liquid phases have the same composition. The large difference between the shapes of curves I and II should not

Table 3: Phase boundaries of ozone/oxygen mixtures.

Temperature		Mol-% ozone	
K	°C	in upper phase	in lower phase
90	−183.2	17.6	67.2
77.5	−195.7	6.9	84.3

Data source: [71, 72]

Table 4: Physical properties of ozone/oxygen mixtures.

Temperature, K	Mass-% ozone in starting mixture	Mass-% ozone in upper phase	Mass-% ozone in lower phase
90.2	24.27	24.27	Only one phase, homogeneous
90.2	25.0	23.92	1.80
90.2	40.0	16.–80	23.20
90.2	50.0	12.04	37.96
90.2	60.0	7.32	52.68
90.2	75.0	0.21	74.79
90.2	75.45	Only one phase, homogeneous	75.45
77.5	10.0	10.0	Only one phase, homogeneous
77.5	25.0	8.10	16.90
77.5	40.0	6.20	33.80
77.5	50.0	4.93	45.07
77.5	60.0	3.67	56.33
77.5	75.0	1.77	73.23
77.5	89.0	Only one phase, homogeneous	89.00

Data source: [73]

come as a surprise because the van der Waals forces between the different types of molecules in the liquid phase (O_2 , O_3) will be quite different (see also Figure 7).

3.1.2 Phase Distribution

The significant structure theory of liquids was applied to the partially miscible system of the O_3/O_2 mixture, which exhibits partial miscibility in a temperature range of 77.6 to 93.2 K (−195.5 to −179.9 °C) [74]. A partition function for the binary liquid mixture was developed using the significant liquid structure theory. A coexistence curve of the O_3/O_2 system was obtained by varying the mol fractions of the components to find the temperature at which the two liquids separate. The agreement between theory and experiment was satisfactory.

3.3 Density and Partial Molar Volumina of Ozone

The density of gaseous ozone at 101 kPa and 273 K is 2.1415 g/L [65]. The density of liquid ozone was measured over a range of 77.4 to 174.2 K using ozone thermometers, and the data are shown in Figure 3. The density of liquid ozone is an almost linear function of temperature [76].

The classical method of calculating coefficients of thermal expansion is by a polynomial equation of the form

$$V = \alpha + \beta T + \gamma T^2 + \delta T^3 + \dots$$

where α , β , γ , and δ are the coefficients, V is the specific volume, and T is the temperature in kelvin. An equation relating the specific volume of liquid ozone to the absolute temperature was determined by the method of least squares. This equation,

$$V = 0.551 + (6.25 \times 10^{-4})T + (3.35 \times 10^{-6})T^2$$

Figure 3: Density of liquid ozone as a function of temperature. (Republished and modified from [76], with permission from © 1957 American Institute of Physics, permission conveyed through Copyright Clearance Center, Inc.)

where V is the specific volume in cm^3/g and T is the temperature in kelvin, is accurate to within 0.2% of the experimental data. From the equation and the table, three coefficients of thermal expansion over the range of 77 to 175 K were derived:

$$\alpha = 0.551, \quad \beta = 6.25 \times 10^{-4}, \quad \text{and} \quad \gamma = 3.35 \times 10^{-6}$$

Table 7: Density of liquid and solid ozone.

Physical state	Temperature		Density
	°C	K	g/cm^3

77.4	−195.7	89.0	92.4	1.5738 ± 0.09			
90	−183.2	95.2	96.8	1.5489			
90	−183.2	100.0	100.0	1.574			
90.2	−182.9	100.0	100.0	1.5727 ± 0.0004			
87.5	−185.6	100.0	100.0	1.5839 ± 0.0011			
77.5	−195.6	100.0	100.0	1.6130 ± 0.0004			
77	−195.5	6.2	9.0	1.230 ± 0.004	Hersh, Berger, and Brown	1959	[66]
77	−195.5	86.8	90.8	1.563 ± 0.005			
90	−183	22.1	29.8	1.245 ± 0.003			
90	−183	63.6	72.4	1.426 ± 0.004			
90	−183	100.0	100.0	1.571 ± 0.003			
85	−188	100.0	100.0	1.595 ± 0.003			
77	−195	100.0	100.0	1.614 ± 0.003			

See also Figure 4

The density of ozone at its boiling point, 161 K, was determined to be $1.354 \pm 0.001 \text{ g/cm}^3$. The volume increase on melting is +7.1% [77]. Additional density data for liquid and solid ozone are listed in Table 7. The densities of ozone/oxygen mixtures are listed in Table 8.

For the conversion of mol-% ozone to mass-% ozone and vice versa in ozone/oxygen mixtures, one can use the following formulas:

$$\text{Mass-\% O}_3 = 100 - \frac{100}{1 + \left(\frac{\text{Mol-\% O}_3}{100 - \text{Mol-\% O}_3} \right) \left(\frac{47.9982}{31.9988} \right)}$$

$$\text{Mol-\% O}_3 = 100 - \frac{100}{1 + \left(\frac{\text{Mass-\% O}_3}{100 - \text{Mass-\% O}_3} \right) \left(\frac{31.9988}{47.9982} \right)}$$

For the interpolation of density as a function of composition relationships, the following equations derived from the foregoing table come in handy:

$$\begin{aligned} \text{at } 77.7 \text{ K} = -195.5^\circ\text{C}: \quad \rho &= 0.833 - 0.213\chi_{\text{O}_3} \\ \text{at } 90.2 \text{ K} = -183.0^\circ\text{C}: \quad \rho &= 0.877 - 0.240\chi_{\text{O}_3} \end{aligned}$$

where ρ is the density in g/cm^3 , and χ_{O_3} is the mass fraction ozone.

It was found that the densities of liquid ozone-liquid oxygen mixtures could be calculated accurately from the additive behavior of densities of pure liquid ozone and liquid oxygen at the same temperature by means of the relation

$$1\bar{d} = \frac{X_1}{d_1} + \frac{X_2}{d_2}$$

where $\bar{d}$ is the density of the mixture, d_1 and d_2 are the densities, and X_1 and X_2 are the weight fractions of pure oxygen and pure ozone, respectively. This linear relationship is also evident from the data illustrated in Figure 4. See also [79].

Figure 4: Density of liquid ozone/oxygen mixtures. (Reproduced and modified from [80].)

3.4 Compressibility of Ozone

Experimental determination of the compressibilities of ozone and ozone/oxygen mixtures would be difficult because of the unstable nature of ozone, so they were calculated from critical constants for pure ozone and from well-established data for oxygen [81]. Equation of state virial parameters of ozone/oxygen mixtures data for pure ozone, pure oxygen, and mixtures containing 20, 40, 60, and 80 mol-% ozone were presented in table format. The calculated compressibilities of pure ozone were used to correct thermodynamic quantities for the ideal gas, computed from spectroscopic data, to real gas conditions.

3.5 Vapor Pressure and Vapor Phase Composition of Ozone

3.5.1 Vapor Pressure of Solid and Liquid Ozone

The vapor pressure between 90.2 and 243.2 K (−183 and −30 °C) can be calculated from the equation [82]

$$\log P = 8.25313 - 814.941587/T - 0.001966943T$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin. The normal boiling point is 161.2 ± 0.3 K (−111.9 ± 0.3 °C). The critical temperature was determined experimentally and found to be 261 ± 0.1 K (−12.1 ± 0.1 °C). The critical pressure derived from this critical temperature and the vapor pressure equation is 5.51 MPa (54.6 atm absolute). Results were in good agreement with the data in the literature. The precision of the vapor pressure data measurement is limited by the unstable nature of ozone and the necessarily small samples that must be used for measurements in the interests in the interests of safety. See also [83].

Vapor pressure data for solid and liquid ozone are listed in Table 9. Figure 5 shows vapor pressure data to higher temperatures, significantly above the normal boiling point.

Table 9: Vapor pressure of ozone.

Physical state	Temperature			Vapor pressure	Authors	Year	References
	K	°C		mm Hg			
Solid at melting point	80.1	−193.0	Triple point	0.00859	Jenkins and Birdsall	1952	[70]
Liquid	90	−183	Boiling point of liquid oxygen	0.10	Jenkins and Birdsall	1952	[70]
Liquid	194.9	−78.2	Dry ice	6.18 atm	Jenkins and Birdsall	1952	[70]
Liquid	87.2	−185.9	Boiling point of liquid argon	4.03×10^{-2}	Hanson and Mauersberger	1985	[84]
Liquid	87.2	−185.9	Boiling point of liquid argon	4.05×10^{-2}	Mauersberger, Hanson, and Morton	1985	[85]
Solid	68	−205		1×10^{-5}	Hanson and Mauersberger	1986	[86]

Figure 5: Vapor pressure of ozone. (Based on data from [82].)

The vapor pressure above liquid ozone was measured with high accuracy in a temperature range of 85 to 95 K. High-precision vapor pressure data will aid research in atmospheric ozone measurements, and ozone/diluent gas streams with known ozone partial pressures will help in calibrating instruments in many laboratory ozone studies such as measurements of cross sections and reaction rates [84, 85]. At the boiling point of liquid argon (87.3 K = -185.9°C), an ozone vapor pressure of 4.03×10^{-2} to 4.05×10^{-2} mm Hg was obtained with an accuracy of $\pm 0.7\%$. Increases and decreases in liquid argon temperatures raised and lowered the ozone vapor pressure, respectively. A least-squares fit of the data provided the Clausius-Clapeyron equation for liquid ozone, and a latent heat of vaporization of 82.7 cal/g was calculated.

Vapor pressures of liquid and solid ozone were measured over a temperature range of 87 to below 66 K. The experiment was performed under flow conditions, and the gas was analyzed by a precision mass spectrometer system to make sure that no premature decomposition had occurred [86]. In the range of solid ozone, two forms, supercooled and crystalline ozone, were found. A least-squares fit of the data for crystalline ozone resulted in the following linear relationship between pressure and the reciprocal of temperature for the crystalline form of ozone:

$$P = 10.460 - 1021.6/T$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin. The estimated uncertainty of the data is $\pm 1.0\%$. A triple point temperature of 79.6 ± 0.3 K was found where supercooled and crystalline ozone data intersect. For example, the vapor pressure of ozone at 68 K (-205°C) is 1×10^{-5} mm Hg, from which the latent heat of sublimation was calculated to be 407 J/g (97.4 cal/g).

The vapor pressure of ozone in a temperature range of 92.8 to 162.0 K can be calculated by the Antoine equation

$$\log_{10}(P) = 4.23637 - [712.487/(T + 6.982)]$$

where P is the vapor pressure in bar and T is the temperature in kelvin (from [87]).

3.5.2 Vapor Pressure and Vapor Phase Composition of Ozone/Oxygen Mixtures

Phase diagrams and vapor pressure composition data for liquid ozone/oxygen mixtures were obtained at 77.6 to 93 K (−195.5 to −180 °C) [88]. The vapor pressure isotherms (Figure 6) were used to construct the boiling point-composition line at atmospheric pressure (Figure 7). The vapor pressure of pure liquid ozone defines an upper limit for the partial pressure of ozone in the vapor in equilibrium with boiling liquid. The vapor pressure of ozone/oxygen solutions deviated markedly from Raoult's law in a positive direction. Liquid-liquid equilibrium indicated that 93 K (−180 °C) was an upper bound for the consolute temperature. The region of two liquid phases extended from 9 to 91 mass-% ozone at 77.6 K (−195.5 °C) and 29.8 to 72.4 mass-% ozone at 90 K (−183 °C).

Figure 6: Vapor pressure isotherms for ozone/oxygen system at three temperatures. (Republished and modified from [88], with permission from © 1955 American Institute of Physics, permission conveyed through Copyright Clearance Center, Inc.)

Figure 7: Phase diagram for ozone/oxygen system at 1 atm total pressure. (Republished and modified from [88], with permission from © 1955 American Institute of Physics, permission conveyed through Copyright Clearance Center, Inc.)

Figure 8: Vapor pressure of ozone/oxygen mixtures at below atmospheric pressure. (Republished and modified from [88], with permission from © 1955 American Institute of Physics, permission conveyed through Copyright Clearance Center, Inc.)

Figure 9: Vapor pressure of liquid ozone/oxygen mixtures at above atmospheric pressure. (Republished and modified from [83], with permission of © 1960 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

Plotting the data from Figure 6 in an Arrhenius-type graph gives straight lines for the logarithm of the vapor pressure when plotted versus reciprocal absolute temperature (Figure 8). This figure is for below atmospheric pressures. A later illustration (Figure 9) shows similar data for above atmospheric pressure.

Figure 10 combines vapor pressure and vapor phase composition data with the phase boundaries in the liquid ozone-liquid oxygen system.

Figure 10: Vapor pressure phase diagram of ozone/oxygen mixtures. (Reproduced and modified from [7].)

3.6 Viscosity of Ozone

The viscosity data for gaseous and liquid ozone are summarized in Table 10. The viscosity of liquid ozone/oxygen mixtures is illustrated in Figure 11. The viscosity of liquid ozone/oxygen mixtures can be interpolated to an accuracy of less than $\pm 5\%$ from the following equations [68]:

$$\log \eta = (\chi_1 \log \eta_{O_2} + \chi_2 \log \eta_{O_3})$$

where χ_1 = mol fraction oxygen, η_{O_2} = viscosity of liquid oxygen = 0.190 cPs at -183°C , χ_2 = mol fraction ozone, and η_{O_3} = viscosity of liquid ozone = 1.56 cPs at -183°C . Similar viscosity data are compiled in Table 11.

Table 10: Viscosity of gaseous and liquid ozone.

Physical state	Temperature		Viscosity		Source	Year	References

Data source: [89–91].

3.9 Critical Constants of Ozone

The critical constants of ozone are listed in Table 14. Chances are that ozone would explode before it reached its critical point when warmed up.

Table 14: Critical point properties of ozone.

Property	SI unit	Other unit
$T_{\text{crit.}}$	261.15 K	-12.1 °C
$P_{\text{crit.}}$	5.514 MPa	54.6 atm
$V_{\text{crit.}}$	147.1 cm ³ /mol	

Data source: [65]

3.10 Solubility, Miscibility, Mixtures, Solutions of Ozone

3.10.1 Mixtures of Inorganic Substances with Ozone

At the temperature of liquid oxygen or liquid nitrogen, liquid ozone and liquid oxygen form two immiscible layers with the lower layer consisting of 30% oxygen dissolved in ozone and the upper layer of 30% ozone dissolved in oxygen. The composition of the two layers varied with temperature. Above a critical temperature for this two-phase phenomenon homogeneous mixtures could be obtained.

3.10.1.1 Solubility of Ozone in Solvents

The solubility of ozone in water is 0.688 g/L at 293 K and 101 kPa and the Bunsen coefficient is 0.321 L gas/L water. This solubility is important for wastewater and drinking water treatment using ozone as the disinfectant. To store dissolved gaseous ozone for later use, perfluorinated organic solvents exhibit high solubility for both oxygen and ozone. The solubility in other solvents has been measured and reported [92]. At one time, dissolved ozone in compressed gas cylinders has been offered for sale for laboratory use where the operation of an ozonizer was not practical.

Ozone forms homogeneous mixtures when mixed with the following chemicals (not all of them oxidizers) in a 1:1 molar ratio at the temperatures (in K) indicated in parentheses following the chemical's formula: CO (77), NF₃ (90), NF₃ (90), CH₄ (90), CClF₃ (90), ClO₃F (116), O₂F₂ (120), CCl₂F₂ (130), ClF₃ (195) [75].

Solutions of ozone in inert halocarbons, such as CF₄, ClCF₃, and CHClF₂, are suitable to measure its spectroscopic properties [93] or as a convenient and safe method to store ozone. Many different inert solvents have been proposed for extraction and storage of ozone. Proposed solvents for the extraction and storage of ozone include CClF₃ or CHClF₂ at <178 K (<-95 °C) [94], mixtures of oxygen and argon [95], mixtures of CCl₂F₂ and CClF₃ [96], and a wide range of 20 different fluorochlorocarbons [97], e.g., CF₄ [98] and CCl₂F₂ [99].

Table 15: Thermodynamic properties of gaseous ozone at pressure of 1 bar.

Data source: [87]

The French company Air Liquide France was one of the first chemical companies to offer ozone solutions commercially for sale. Ozone can be stored in solution under high pressure [100]. It is recommended to store these compressed gas cylinders below 250 K = -23°C to extend the shelf life of this chemical. As an alternate solvent, anhydrous white fuming nitric acid has been patented as a solvent for gaseous ozone [101]. This would make a good rocket propellant oxidizer.

It was discovered that a low concentration of CF_3Cl (Freon-13) on the order of 3 to 5 mass-% added to ozone/oxygen solutions completely eliminated the two-phase regions [17]. Thus, it became possible to handle these solutions without the dangers that would attend the separation of an ozone-rich phase.

3.11 Thermodynamic Properties and Thermal Properties of Ozone

The thermodynamic properties of gaseous ozone are listed in Table 15. The data in the NIST online table [87] go all the way to 6000 K, but ozone would not be stable at those temperatures. Only the data below 1000 K are shown.

3.11.1 Heat Capacity of Ozone

The specific heat of liquid ozone has been measured over a temperature range of 97 to 121 K. The heat capacity was found to be a linear function of temperature and could be represented by the equation

$$c_p = 0.425 + 0.0014(T - 90)$$

where c_p is the heat capacity in $\text{cal g}^{-1}^{\circ}\text{C}^{-1}$ and T is the temperature in K [102]. This equation was considered sufficiently accurate for engineering purposes over the temperature range of 90 to 150 K. Thus, the values reported for the specific heat of liquid ozone at 90 and 150 K in the following table (Table 16) are compatible with the preceding equation.

Table 16: Heat capacity of liquid ozone.

Temperature		Heat capacity			
K	$^{\circ}\text{C}$	$\text{J mol}^{-1} \text{K}^{-1}$	$\text{J g}^{-1} \text{K}^{-1}$	$\text{cal mol}^{-1}^{\circ}\text{C}^{-1}$	$\text{cal g}^{-1}^{\circ}\text{C}^{-1}$
90	-183	85.35	1.7782	20.39	0.425

Data source: [65, 87]

3.11.3 Heat of Fusion and Solid-State Phase Transitions of Ozone

The heat of fusion $(\Delta H)_{\text{melt}}$ of solid ozone was estimated at about 2.09 kJ/mol = 0.5 kcal/mol [65].

3.11.4 Heat of Vaporization of Ozone

Heat of vaporization data for liquid ozone are listed in Table 18.

Table 18: Heat of vaporization of liquid ozone.

Heat of vaporization ^a $(\Delta H)_{\text{vap}}$				Source	Year	References
kJ/mol	kcal/mol	J/g	cal/g			
15.19	3.63	316.4	75.63	Hersh	1959	[103]

^a At normal boiling point

Molecular mass: 47.9982 g/mol

A latent heat of vaporization of liquid ozone of 82.7 cal/g was calculated from vapor pressure data [84]. The latent heat of sublimation of solid ozone was calculated to be 407 J/g (97.4 cal/g) [86]. See also [83].

3.11.5 Heat of Dissociation of Ozone

The activation energy of thermal decomposition of gaseous ozone at low pressure is 100.4 kJ/mol = 24.0 kcal/mol [65]. The bond dissociation energy of 105 kJ/mol (25 kcal/mol), defined as the energy necessary to break the first bond, is far less than

the mean thermochemical value of 299 kJ/mol (71.5 kcal/mol). The bond dissociation energy and the activation energy are essentially identical.

3.11.6 Entropy of Ozone

Thermodynamic functions of ozone are listed in Table 19.

Table 19: Thermodynamic functions of gaseous ozone.

3.12 Molecular Properties, Structure, Dipole Moment, Molecular Orbital Calculations of Ozone

3.12.1 Molecular Properties of Ozone

The molecular structure of ozone is an open V, as shown in Figure 12. The V-shape structure of ozone (116.8° bend angle and 1.27 Å bond distance) is well established. The

Figure 12: Open-form and fundamental vibrations of ozone molecule. (Reproduced from [105] with permission © Uspekhi Fizicheskikh Nauk 1994.)

microwave spectrum gives structural information that can be interpreted unambiguously and that is more accurate than that obtained by other methods. The rotational spectra have been obtained for six different isotope-labeled ozone molecules between 9 and 45 GHz [104]. Although the resultant bond length of $1.278 \pm 0.002 \text{ \AA}$ was consistent with the electron diffraction value of $1.26 \pm 0.02 \text{ \AA}$, the apex angle value of $116^\circ 45' \pm 30'$ was inconsistent with the diffraction value of $127 \pm 3^\circ$. The dipole moment of ozone was determined to be 0.58 ± 0.05 Debye unit from the Stark effects of two low J-transitions.

However, there is some evidence of an alternate form of the ozone molecule in the shape of a closed equilateral triangle (Figure 13), which may be an intermediate in the decomposition or formation of bent (V-shaped) ozone. This isomer is referred to as the metastable cyclic isomer of ozone, or cyclic ozone. Theoretical evidence for the stability of cyclic ozone has been conflicting [106–108]. The cyclic ozone should decompose more easily than the bent ozone because it contains three single bonds. The $\angle \text{O—O—O}$ bond angle in the triangular form should be close to 60° . This molecule is isoelectronic with cyclopropane.

Figure 13: Molecular structure of cyclic ozone.

Because oxygen as a starting material is in abundant supply, oxygen-derived high-energy rocket propellants have received significant attention in recent decades. Theoretically, the cyclic form of ozone is an even more powerful oxidizer than conventional ozone. The predicted enthalpy of formation of cyclic ozone vapor is above that

of V-shaped ozone with an angle of $116^{\circ}48'$, which is $+142.7\text{ kJ/mol}$. Theoretically, the cyclic structure is energetically more favorable by 200 kJ/mol (48 kcal/mol), contrary to the value obtained in experiments [109]. The theoretical enthalpy of reaction of metastable cyclic solid ozone with liquid hydrogen is 17.15 MJ/kg (going to water vapor), compared to 14.65 MJ/kg for frozen normal ozone/LH2 compared to only 12.56 MJ/kg for LOX/LH2, which is what is currently flying in many rockets. Other *ab initio* calculations predicted that the energy level of the cyclic conformer of ozone should be 67 kJ/mol (16 kcal/mol) above the preferred (open-chain) form of this substance. The theoretical rocket performance of cyclic ozone is about 35% higher than that of LOX/LH2 [110]. That should be enough motivation to continue to search for more energetic forms of oxygen and/or ozone [111]. The cyclic ozone should decompose more easily than the V-shaped bent ozone because it contains three single bonds.

Several *ab initio* quantum mechanical investigations have predicted that the stability of the cyclic ozone molecule may be sufficient for future use as a rocket propellant, indicating that a significant energy barrier prevents its spontaneous conversion to the open form, and an even bigger barrier prevents its decomposition to dioxygen and atomic oxygen [112, 113]. *Ab initio* calculations of the equilibrium structure of the D_{3h} form of ozone and the energy difference (ΔE) between the open and cyclic forms of ozone indicated that ΔE is 121.7 kJ/mol (29.1 kcal/mol), of which triple excitations contributed 24.3 kJ/mol (5.8 kcal/mol) [114]. Zero-point vibrational energies decreased ΔE by 1.67 kJ/mol (0.4 kcal/mol), yielding a final estimate of 120 kJ/mol (28.7 kcal/mol). These results demonstrated that cyclic ozone is above the

dissociation limit ($109.2\text{ kJ/mol} = 26.1\text{ kcal/mol}$). The existence of a cyclic ozone seems proven because cyclic ozone rings were found adsorbed to a magnesium oxide surface using transmission electron diffraction [115]. The first experimental evidence of the cyclic form of ozone was found in three air-stable surface reconstructions of MgO (111) surfaces on single crystals annealed above 1450°C . The oxygen trimers appeared to be centered over underlying Mg atoms. Charge transfer may explain the cyclic O_3 stabilization of the polar MgO (111) surface, and it may not be possible to remove cyclic O_3 from the surface and into a rocket without it suffering premature decomposition. But most investigations into the short-lived existence of cyclic O_3 and ways to stabilize it were initiated by studies of the formation and decomposition in Earth's atmosphere, and only few had the use of ozone as a rocket propellant in mind.

If ring-shaped polyoxygen molecules contain more than three oxygens, the strain energy would decrease, and the stability should increase [116]. In analogy of dioxygen forming a dimer $(\text{O}_2)_2$, ozone may also exist in the form of a dimer $(\text{O}_3)_2$ [117].

The half-life of cyclic ozone was estimated to be only 10 s at 200 K and 70 s below 100 K, which might partly explain the unsuccessful attempts for its experimental identification [118]. The kinetic isotope effects (KIEs) for various ^{18}O substitution reactions were calculated as a function of temperature and were predicted to be as high as

10 at very low temperature. Because of the large KIEs, the experimental identification of cyclic $^{18}\text{O}_3$ seems more promising than cyclic $^{16}\text{O}_3$.

From a propulsion standpoint, the biggest question with cyclic ozone is how to make it. Some researchers are pursuing cyclic ozone production via organometallic chemistry using a transition metal ligand to bind and stabilize the cyclic ozone molecule. Cyclic ozone has not been isolated so far, despite its computed kinetic persistence. Possibilities of “trapping” this molecule (or the valence-isoelectronic cyclic thiozone, S_3) in transition metal complexes were investigated.

In 2005, Temple University’s Center for Advanced Photonics Research was awarded a Defense Advanced Research Projects Agency (DARPA) grant to develop cyclic ozone using laser-based chemistry methods [119]. They calculated the lifetime of cyclic ozone to be essentially infinity at liquid nitrogen temperatures. Whether this molecule is stable or sensitive to spontaneous explosion remains unknown. Coherent anti-Stokes Raman spectroscopy (CARS) schemes for detecting the synthesis of cyclic ozone were suggested.

A fourth allotropic form of oxygen is called tetraoxygen (O_4 , oxozone), most likely a dimer of dioxygen (O_2)₂, with potentially even higher rocket performance than the ozones. Very little is known about tetraoxygen. The exact shape of this molecule is still uncertain, but *ab initio* calculations indicate that some forms of the O_4 molecule should be stable. Best estimates based on *ab initio* calculations estimated an enthalpy of formation in a range of 93–95 kcal/mol [120]. The existence of tetraoxygen was predicted theoretically in the 1920s, and recent experiments have demonstrated its existence. The various aspects of tetraoxygen relate closely to ozone chemistry. A metastable energized state of tetraoxygen at low pressure was detected experimentally in 1997 [121].

A metastable state of tetraoxygen was produced and directly detected in a molecular beam, both by means of a direct-current discharge and by photodissociation of ozone in the collision region [121]. The O_4^* produced a complex spectrum from which general conclusions were drawn about its energetics and structure. The energy for this species is about 4 eV above that of two isolated O_2 molecules. A predominance of peak frequency differences in the range 411–419 cm^{-1} supports a cyclic D_{2d} geometry as predicted by *ab initio* calculations. Evidence of solid tetraoxygen was found at extremely high pressures (about 20 GPa) [122]. Intact O_4 as a gas-phase species had a lifetime in excess of 1 μs , and its dissociation requires overcoming a barrier on the order of 42 kJ/mol (10 kcal/mol) [123].

Condensation of gaseous ozone at 10–20 K gave solid ozone, which was used for X-ray diffraction (XRD) and neutron powder diffraction analysis. The solid had a bent structure with an O—O—O angle of 117.9°, in good agreement with the gas-phase structure. Measurement of the unit cell dimensions over the range 5–54 K provided no evidence for a phase transition. The crystal structure of ozone was determined from conventional XRD and high-resolution neutron powder diffraction data [124]. Ozone crystallizes in the orthorhombic space group P_{bca} with eight formula units per unit

cell. The lattice parameters at 5 K are as follows: $a = 778.88(2)$ pm, $b = 669.73(2)$ pm, $c = 684.13(2)$ pm. The geometry determined for an ozone molecule in the solid was found to be in good agreement with the well-known gas phase structure. There was no significant deviation from ideal C_{2v} symmetry. An ozone dimer with C_i point symmetry is feasible.

The $(O_3)_2$ dimer potential energy surface was explored by *ab initio* calculations, identifying five minima with binding energies between 1.46 and 9.37 kJ/mol (0.35 and 2.24 kcal/mol) [125]. The most stable may be characterized as slipped parallel, with the two O_3 monomers situated in parallel planes.

3.12.1.1 Search for Other Polyoxygens in Frozen Ozone

The search for higher polyoxygens and the triangular form of ozone has concentrated on frozen ozone, prepared in various ways and kept at very low temperatures, often in a matrix of frozen oxygen or frozen argon. One had to rely on spectroscopic methods to determine if the frozen mass contained anything other than frozen ozone.

Solid oxygen can serve as a matrix and stabilizer for solid ozone and other polyoxygens (if they exist) [126]. Experiments of this type were part of the development of rocket propellants that significantly improve the performance of the conventional liquid oxygen rocket propellant. One of the species believed to exist in frozen ozone was a weakly bound $O \cdots O_3$ complex isolated in solid oxygen, but later experiments suggested the Fourier transform infrared (FTIR) absorption spectra to be due to an ozone dimer formed by nanosecond tunable UV laser light irradiation between 210 and 240 nm to generate specifically oriented ozone dimers in solid oxygen. Other absorptions are due to defect sites, and they disappear during annealing [127]. Ozone was either generated *in situ* by irradiation of frozen oxygen or deposited onto a cold finger from a stream of oxygen seeded with low concentration of ozone [128, 129].

Cyclic O_4 is of interest both as a potential high-energy-density material (HEDM) species and because of its possible role in the ozone deficit problem in atmospheric chemistry. The pathway for decomposition from the D_{2d} minimum through a saddle point of C_2 symmetry and the approximate location of the singlet triplet crossing were calculated by computing the triplet energies at the geometries along the pathway for the singlet state [130]. The barrier to decomposition was found to be about 9 kcal/mol.

In preparation for inverse hybrid engine tests with frozen ozone/frozen oxygen in the chamber and gaseous hydrogen injected as a fuel, rocket engine tests with frozen oxygen (no ozone yet) were conducted at US Air Force Research Laboratory (AFRL), Phillips Laboratory at Edwards Air Force Base. An inverse hybrid rocket engine developed at Orbitec using a grain of solid oxygen burning in an atmosphere of gaseous hydrogen was tested at AFRL. In an effort to achieve higher I_{sp} , it was planned to replace the solid oxygen grain with a grain composed of solid oxygen enriched with solid ozone. Before this test could be done, the safety properties of solid oxygen-solid ozone mixtures had to be characterized [131, 132].

3.12.2 Dipole Moment of Ozone

Two properties, the dipole moment and the magnetic susceptibility of ozone, were of special interest for the characterization of the ozone molecule. A fully symmetrical (triangular) molecule should not have a dipole moment. The dipole moment, which was very important in the long debate about the structure of the ozone molecule, was first reported in 1939 using conventional methods on the liquid ozone/oxygen mixture obtained from condensation of the product of silent discharge with liquid oxygen [133]. The value of 0.49 D ruled out linear and symmetrical triangular structures for ozone.

From the Stark splitting of a microwave spectrum, the dipole moment was derived to be 0.53 ± 0.02 debye. Zeeman splittings of this transition showed that ozone is not significantly paramagnetic [134].

The dipole moment of ozone was determined to be 0.58 ± 0.05 debye from the Stark effects of two low J transitions in the microwave spectrum [104].

3.12.3 Molecular Orbital Calculations of Ozone

Because ozone is often too unstable to allow detailed experimental determination of many of its molecular properties, computational chemistry has stepped in to fill the gap. Predicted absorption spectra of open-form V-shaped O_3 and its excited states and predissociation states and those of postulated cyclic ozone can then be compared to measured spectra. The vibrational energies of ozone up to the dissociation threshold were calculated and compared to measured spectra [135]. The three lowest transition energies predicted for $^{16}O_3$ are 1101.9 cm^{-1} (1103.14 cm^{-1}), 698.5 cm^{-1} (700.93 cm^{-1}), and 1043.9 cm^{-1} (1042.14 cm^{-1}) for the symmetric stretch, the bending, and the antisymmetric stretch modes, respectively. The numbers in parentheses are the experimental values.

The effective ground state potential energy function of the ozone molecule near the C_{2v} equilibrium configuration was obtained in a least-squares fit to the largest sample of experimental, high-resolution vibration-rotation data used for this purpose so far [136]. The long-range behavior of the fitted potential at the dissociation limit $O_3 \rightarrow O_2 + O$ showed very good agreement with experimental data. The new potential energy surface was used to predict the band centers of the isotopomers $^{17}O_3$ and $^{18}O_3$.

3.13 Absorption, Emission, and Fluorescence Spectra of Ozone

The spectra of ozone are extremely important in determining its prevalence in the atmosphere, either as an air pollutant near the surface or as the key ingredient of the ozone layer in the upper atmosphere that protects us from the damaging UV radiation of the Sun. Spectroscopy would also be the method of choice to identify contaminants in liquid ozone, some of which are responsible for its hazardous explosion sensitivity. Spectroscopy is used to identify kinetic mechanisms that lead to the formation

of ozone or its decomposition and to identify intermediates in those reactions. Isotopic labeling and comparison of spectra of labeled compounds with natural ozone is a frequently used method to assign frequencies in the spectra to specific vibrations in the molecule and clarify its structure and energy levels. If we are looking for superoxidizers like O_4 , O_6 , or O_8 as future rocket propellants, the best way to find them is to predict from quantum mechanical calculations what their spectra might look like and then start looking at the predicted frequencies of molecular vibrations, rotations, or electronic levels. If ozone is in use at the workplace (any workplace, not just rocket test sites), the ozone concentration in the air needs to be monitored to protect the workers and spectroscopic methods are the fastest and most accurate methods to do that, even by remote sensing without direct contact with the sample.

3.13.1 Visible-Range Absorption Spectra of Ozone

The extinction coefficients of ozone dissolved in liquid oxygen or a Freon 12/13 mix at 77 K in the visible range were compared to the extinction coefficient of gaseous ozone in air (Table 20).

Table 20: Molar extinction coefficients of dissolved ozone.

Solvent	Temperature, K	Molar extinction coefficient, $L\ cm^{-1}\ mol^{-1}$	
Freon mixture	77	2.81 at 570 μm	3.10 at 600 μm
Liquid O_2	77	1.44 at 560 μm	2.00 at 600 μm
Gaseous	295	1.23 at 575 μm	1.32 at 605 μm

Data source: [93]

As shown in Table 20 and Figure 14, the molar extinction coefficient of ozone was greatest when dissolved in the Freon mix. The molar extinction coefficient of liquid ozone at 77 K was greater than that of gaseous ozone at 295 K.

3.13.2 Infrared Absorption Spectra of Ozone

In view of the great significance of ozone in atmospheric chemistry, and the use of IR spectroscopy for remote sensing, IR spectra of ozone have been thoroughly investigated. A low-resolution IR spectrum of gaseous ozone is shown in Figure 15. See also [137, 138].

Fourteen IR absorption bands of ozone between 500 and $3300\ cm^{-1}$ were measured and identified and values of the vibrational anharmonic constants determined [140]. The integrated band absorbances of many of these bands were measured from spectra taken on a spectrometer with a 32-m optical path length sample cell near 298 K

Figure 14: Ozone light absorption spectra in visible range. (Republished and modified from [93], with permission granted by © 1961 American Institute of Physics; permission conveyed through Copyright Clearance Center, Inc.)

(25°C). It was shown that the statistical band model described the behavior of the bands reasonably well for the ranges of experimental variables used.

A very complete history of the development of IR and microwave (vibrational-rotational) spectroscopy of ozone from the mid-19th century to 1994, including a bibliography of 254 references, was offered in [105]. It covered the development of both linear and non-linear spectroscopy and applications in fields of physics and chemistry of ozone, monitoring in the atmosphere, laser stimulation of chemical reactions, and study of relaxation processes.

IR spectra have helped to identify cyclic ozone, an unstable isomer of the open-chain normal ozone [141, 142]. The extinction coefficient of gaseous ozone in the IR range at 9.49μ is $80\text{ cm}^{-1}\text{ mol}^{-1}\text{ L}$.

Figure 15: Low-resolution IR spectrum of gaseous ozone. (Reproduced and modified with permission from [139].)

A review of efforts to experimentally determine absolute line intensities for ozone transitions in the 9- to 11- μm spectral region over the last several decades explained that much of this effort has been driven by the requirements for remote sensing of terrestrial atmospheric ozone [143]. While significant progress has been achieved, discrepancies continue to persist among various IR measurements, and the relation between IR and UV standards is vague.

The IR spectra of liquid ozone films were measured at 78–85 K and ozone dissolved in liquid argon at 91–95 K [144]. Maxima of ozone bands in Ar solution were shifted toward lower frequencies compared to those in the gas phase by 1–30 cm^{-1} .

3.13.2.1 Infrared Absorption Band Assignments to Fundamental Vibrations in Ozone
Calculations of vibrations leading to the decomposition of ozone using valence-force potential functions tried to explain how molecules become energized in events leading to monomolecular decomposition reactions [145].

Some of the isotopic ozone molecules of different combinations of oxygen-16 and oxygen-18 have been synthesized and isolated in rare-gas matrices at 20 K and their IR absorption bands identified [146]. The isotope effects were calculated for symmetrical as well as unsymmetrical isotopic ozone molecules.

The vibrational frequencies of the six antisymmetric stretching modes of the ozone isotopomers $^{16}\text{O}_3$, $^{16}\text{O}_2^{18}\text{O}$, and $^{18}\text{O}_3$, in both Ar and Kr matrices, have been measured [147]. The ozone molecule has very anharmonic antisymmetric vibrations compared to other known molecules. Upper and lower limits to the valence bond angle were calculated and compared to each other and to the gas-phase bond angle. The bond angles of O_3 in both Ar and Kr, which were derived from measured

frequencies agreed with one another within the experimental uncertainty ($\pm 0.4^\circ$), and these angles were also in agreement with the gas-phase angle, $116.8 \pm 0.5^\circ$.

FTIR spectra of six ozone isotopomers of ^{18}O -enriched ozones were studied in LOX solution at 77 K in the spectral range $650\text{--}3200\text{ cm}^{-1}$ [148]. Full vibrational assignments could be made, and relative transition strengths were measured for many previously unobserved absorption bands of ^{18}O -enriched species.

3.13.3 Raman Fluorescence Spectra of Ozone

The problem with Raman spectroscopy of ozone is that ozone photolyzes under the influence of exciting illumination before fluorescence spectra can be recorded. It is therefore best to keep the ozone cool in a matrix of a frozen inert gas while the Raman spectra are recorded.

The Raman spectra of argon matrix-isolated ozone and oxygen-18-enriched ozone were obtained using reduced-power argon ion laser excitation [149]. Photodecomposition of ozone was sufficiently moderated to obtain excellent Raman spectra, with the following $^{18}\text{O}_3$ assignments: ν_1 1104 cm^{-1} , very strong; ν_2 701 cm^{-1} , strong; ν_3 1038 cm^{-1} , weak. IR spectra provided complementary data. An ozone valence angle of $116.3 \pm 4^\circ$ was calculated, in excellent agreement with microwave results. See also [150].

3.13.4 Ultraviolet/Visible Range Absorption Spectra of Ozone

The problem with measuring the UV spectra of ozone is that ozone photolyzes under the influence of a light beam before absorption spectra can be recorded. Strangely enough, not even the NIST Chemistry WebBook web site has UV spectra of O_3 . It is therefore best to keep the ozone cool in a matrix of a frozen inert gas while the spectra are recorded. For the visible region, some references about experimental absorption measurements are very old since the first absorption spectrum (between 520 and 650 nm) was observed by Chappuis in the year 1880, and this absorption range was named after him. Only with improved instrumentation was it possible to obtain accurate measurements of the absorption coefficient of ozone in the visible and UV ranges [151].

The absorption coefficient of gaseous ozone was measured for mercury lines at 2537, 2894, 2967, 3021, 3342, and $5770\text{ \AA}$ by measuring both the optical absorption and the pressure rise as the ozone decayed in a sealed quartz absorption tube [152]. This avoided a chemical determination of the ozone. The absorption cross-section σ is related to the absorption coefficient α by the equation $\sigma = \alpha/N$, where N is the atomic number density.

The absorption coefficients of ozone have been measured in the UV and visible regions using essentially 100% pure ozone [153]. The technique was based on a pure preparation of O_3 . Owing to the low variation of pressure in the cell, the ozone decom-

position was assumed to be negligible. Measurement of ozone concentration would then be a simple measurement of the total pressure.

The ozone absorption cross section at the 253.7 nm mercury line was measured very accurately and can be used as a reference line for other measurements. The partial pressure of ozone in the absorption cell was measured by simultaneously measuring the composition of the mixture (O_2/O_3) with a mass spectrometer and the total pressure of the gaseous system with a calibrated pressure sensor [154]. The method was precise but involved lots of instrumentation and is limited to measurements at some specified wavelengths.

Absorption cross sections of ozone at ambient temperature for the whole spectral region within the 195- to 345-nm range were measured and compared with all of the previous data [155]. The agreement among more recent works was relatively good. The absorption spectrum of ozone in the UV region (Figure 16) shows a large continuum from 200 to 350 nm with a maximum near 250 nm (Hartley band) on which some small diffuse undulations spaced by approximately 200 cm^{-1} can be seen. At the higher wavelengths (310–350 nm), the spectrum is dominated by more intense but also diffuse vibrational bands corresponding to the Huggins bands. At the mercury resonance line wavelength ($\lambda = 254\text{ nm}$), the value $\sigma(O_3)$ was found to be $1.130 \pm 0.011 \times 10^{-17}\text{ cm}^2$.

Figure 16: Absorption cross sections of ozone in UV. (Republished and modified from [155], with permission of © 1991 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

Absolute absorption cross sections of ozone have been measured at ambient (295 K) and low temperature (218 K) in the visible region. The temperature effect was very small. Ozone has an absorption band between 420 and 830 nm, with a large continuum with two maximum absorptions, $\sigma = 4.83 \times 10^{-21}\text{ cm}^2$ at 575 nm and $\sigma =$

Figure 17: Absorption cross sections of ozone in the visible range at ambient temperature. (Republished and modified from [156], with permission of © 1998 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

$5.23 \times 10^{-21} \text{ cm}^2$ at 603 nm, overlapped by diffuse vibrational structure (Figure 17) [156]. The minimum of the absorption between the Hartley and the Chappuis bands was observed for the first time at 377.5 nm.

The extinction coefficient of gaseous ozone in the UV range at 252 nm, where the absorption is very strong, is $3360 \text{ cm}^{-1} \text{ mol}^{-1} \text{ L}$. This is what protects us from even worse sunburns, but enough UV is coming through to pose a skin hazard.

3.13.5 Microwave Absorption Spectra of Ozone

The microwave spectra give structural information that can be interpreted unambiguously and that is more accurate than that obtained by other methods. Microwave spectra in the region of four low- J rotational transitions of $^{16}\text{O}_3$ were measured in the region from 42 to 118 GHz, and the rotational spectroscopic constants found were $A = 106530.0 \pm 1.1 \text{ MHz}$, $B = 13349.06 \pm 0.06 \text{ MHz}$, $C = 11834.3 \pm 1.1 \text{ MHz}$. The oxygen nuclei form an isosceles triangle (which is a triangle that has two sides of equal length) with an apex angle of $116^\circ 49' \pm 30'$, and the two equal internuclear distances are $1.278 \pm 0.003 \text{ Å}$ [134]. The dipole moment was derived from the Stark splitting to be 0.53 ± 0.02 debye. Zeeman splittings of this transition showed that ozone is not significantly paramagnetic.

The rotational spectra of six isotope-labeled ozone molecules were measured between 9 and 45 GHz [104]. The spectra of four of the molecules have been identified to the extent necessary to determine the spectral constants, from which moments of inertia have been calculated. The structural parameters of the molecules were calculated by taking the moments of inertia for a molecule two at a time (Section 3.12).

The microwave spectrum of O_3 was reanalyzed to include the effect of centrifugal distortion [157]. The rotational constants determined in this manner were $A = 106534.74$ MHz, $B = 13348.95$ MHz, $C = 11834.30$ MHz. The force constants were then used to calculate distortion constants for $^{16}O^{18}O^{16}O$, and these in turn were used to analyze its rotational spectrum. See also [158–162].

3.14 Dielectric Constant of Ozone

Numerical data for the dielectric constant of liquid ozone are listed in Table 21, and the dielectric constants of liquid ozone/oxygen mixtures are listed in Table 22.

Table 21: Dielectric constant of liquid ozone (at 1 kHz).

Temperature		ϵ	Temperature		ϵ
K	°C		K	°C	
77	–195	5.45	147	–126	3.33
90	–183	4.75 ± 0.02	162	–111	3.01
103	–170	4.33	175	–98	2.91
118	–155	3.85	185	–88	2.78

Data source: [103], as referenced in [65]

Table 22: Dielectric constant of liquid ozone/oxygen mixtures (at 90 K = –183 °C).

Ozone in oxygen		Dielectric constant ϵ (dimensionless)	Molar polarization, cm^3
Mass-% O_3	Mol-% O_3		
0	0	1.46 ± 0.01	—
14.9	10.5	1.82	26.352
17.6	12.5	1.90	26.296
19.2	13.7	1.93	25.642
29.8	22.1	2.20	23.774
100.0	100.0	4.75 ± 0.02	—

Data source: [103, 133]

3.15 Magnetic Properties of Ozone

It is interesting to note that in contradistinction to oxygen, ozone is not paramagnetic. The paramagnetic properties of ozone/oxygen mixtures can be used to analyze the composition (as long as no other diluents are in the mixture) (Section 4.1.2.6).

The data needed for the analysis of liquid ozone/oxygen mixtures by measurement of magnetic susceptibility were determined by the Quincke (U-tube) method for

magnetic susceptibility with a permanent magnet [163]. Results at 78 K (−195 °C) and 90 K (−183 °C) showed a linear relation between the magnetic susceptibility of the solutions and mass percentage oxygen at low oxygen content. Above about 10% oxygen the specific susceptibility of oxygen in solution decreased significantly. At 90 K (−183 °C), the ratio of specific susceptibility of oxygen in solution to that of pure liquid oxygen decreased from 1.30 at low concentrations to 1.13 at 27.6% oxygen, the two-liquid phase boundary. The limiting ratio at 78 K (−195 °C) was 1.42. The discontinuity in magnetic susceptibility was used to establish the compositions at the phase boundaries, 9.2 and 91 mass-% oxygen at 78 K (−195 °C), 27.6 and 70.2% at 90 K (−183 °C).

The magnetic susceptibility of gaseous ozone was reported as 0.002×10^{-6} centimeter gram system (CGS) units and that of liquid ozone was 0.150×10^{-6} CGS units (from [7] as referenced in [65]). For comparison, the magnetic susceptibility of liquid oxygen is 260×10^{-6} CGS units.

4 Chemical Properties of Ozone

4.1 Chemical Reactivity of Ozone

At ordinary temperatures, ozone is a gas, light blue in color. When inhaled, the gas has a characteristic pungent odor from which its name was derived from the Greek word *ozein*, to smell. The odor permits recognition of ozone in concentrations down to about 0.1 ppm. Gaseous ozone is a highly active, irritating, oxidizing substance. Ozone is a strong oxidizer. Its oxidizing power liberates elemental iodine from an acidified aqueous potassium iodide solution. The addition of a trace amount of starch makes this popular test even more sensitive when the iodine-starch adduct turns dark blue. Often potassium iodide/starch paper is available from chemical supply houses and can be used to detect ozone leaks. An excellent summary of the chemical and catalytic properties of ozone and its participation in many different types of reactions was published with many literature references [164].

Gaseous ozone does not react with hydrogen gas at 195 to 294 K (−78 to +21 °C) and 67 to 141 kPa (504 to 1061 mm Hg). In a range of 195 to 273 K (−78 to 0 °C) ozone will initially not visibly react with cyanogen or nitrous oxide. At 296 K (23 °C) and 74 kPa (557 mm Hg), ozone will react slowly with cyanogen over the course of 18 h. Ozone will explode when mixed with carbon monoxide, nitric oxide or phosphine at 195 K (−78 °C). Ozone will immediately explode if mixed with ammonia at 273 K (0 °C). On the other hand, at lower temperatures, it has been postulated that *ammonium ozonide* is formed by the slow oxidation of solid NH_3 by gaseous O_3 at low temperatures [165]. It proceeds through an unstable intermediate:

A red solid appears on warming around 143 K (-130°C), reaches a maximum concentration at $\sim 158\text{ K}$ ($\sim -115^{\circ}\text{C}$), and is entirely decomposed as soon as the mixture warms to 183 K (-90°C). The IR spectra show two strong bands at 800 and 1140 cm^{-1} and two faint ones at 1260 and 2053 cm^{-1} , besides the characteristic bands of the NH_4^+ and NO_3^- ions. The explosion properties of the frozen mixture have not been established.

Liquid ozone is stable toward and miscible with liquid methane (at 90 K = -183°C), liquid fluorine (at 77 K = -196°C), liquid oxygen difluoride (at 77 K = -196°C), and liquid nitrogen trifluoride (at 90 K = -183°). With perchloryl fluoride it is miscible at 116 K = -157°C but no longer miscible at lower temperatures at 90 K = -183°C . Ozone dissolves in halocarbon-12 (Cl_2CF_2) or halocarbon-13 (ClCF_3) at 116 K = -157°C without reactions [99]. The saturation concentration of ozone in tetrafluoromethane at 90 K = -183°C is 12 mass-% O_3 [98]. The saturation concentration of ozone in liquid argon at 90 K = -188°C is only 10 mass-% O_3 . Mixtures of liquid nitrogen and liquid ozone separate at 77 K = -196°C into two phases. The upper phase contains 5.1 mol-% O_3 , and the lower contains 8.8 ± 0.9 mol-% nitrogen. Ozone is completely homogeneously miscible with ozone fluoride O_3F_2 at 90 K = -183°C , and ozone fluoride decomposes only slowly at these temperatures in ozone solutions. However, if the mixture is warmed to 116 K = -157°C , it will explode.

Whereas ozone is miscible with oxygen difluoride OF_2 , its miscibility with dioxygen difluoride O_2F_2 is only limited. A homogeneous mixture can be obtained at 116 K = -157°C , but when this mixture is cooled to 90 K = -183°C , the O_2F_2 precipitates as a solid, and if one attempts to warm the mixture to 195 K (-78°C), it will explode. Ozone does not mix with chlorine trifluoride at 133 K = -140°C .

4.1.1.1 Alkali Metal Ozonides

It would be nice if the alkali metal or tetraalkylammonium ozonides could be stabilized and used as a storable stable solid form of ozone. Alkali metal ozonides form as deep orange compounds by the reaction of ozone with alkali metal (Na, K, Rb, Cs) hydroxides or the metals themselves. It would be possible to obtain 93% pure KO_3 by exposing dry powdered KOH to oxygen containing 6–8% ozone at 263 to 258 K (-10 to -15°C) [166]. The product was extracted with liquid ammonia to yield red-brown needles of KO_3 . KO_3 decomposed completely in 11 d in the following manner:

The enthalpy of formation of KO_3 was estimated as $+260 \pm 4\text{ kJ/mol}$ ($+62.1 \pm 0.9\text{ kcal/mol}$). The molecular structure of alkali metal ozonides contains an O—O—O linkage. Ammonium ozonide, formed as an orange solution from bubbling ozone in oxygen into liquid ammonia, is thermally unstable and decomposed to ammonium nitrate, oxygen, and water. Ozonides have been treated as solid propellant oxidizers, but experiments failed to produce enough stable materials to actually fire it in a rocket engine.

KO_3 dissolved in liquid NH_3 absorbs strongly in the UV from 300 nm, in addition to the strong band in the visible violet-blue range [167]. Other species, such as O_3 , O_2^- , and HO_2 , also absorb in that region.

4.1.1.2 Reactions of Ozone with Inorganic Compounds

Ozone will burn with hydrogen gas if the mixture is ignited, but at low temperatures with liquid ozone, a new type of chemistry of peroxides and superoxides begins to unfold. The composition of low-temperature condensates obtained by the reaction of hydrogen atoms with liquid ozone has been determined from the Raman spectra and data of the molar ratio of O_2 to H_2O_2 in the decomposition products [168]. The main constituents are hydrogen tetroxide, H_2O_4 , hydrogen trioxide, H_2O_3 , and hydrogen peroxide, H_2O_2 , in comparable amounts, and some water, H_2O . H_2O_4 , H_2O_3 , and H_2O_2 are formed in diffusion-controlled reactions between OH and HO_2 in the liquid ozone layer and stabilized by transfer to the solid phase. $\cdot\text{OH}$ and $\cdot\text{O}_2\text{H}$ radicals are generated via a sequence of the reactions initiated by the interaction $\text{H} + \text{O}_3(\text{L})$.

4.1.1.3 Reactions of Ozone with Organic Compounds

Ozone will react with many organic compounds under the destruction of the carbon skeleton. The destruction of organic matter is the key mechanism for the bactericidal and disinfecting properties of ozone. Such reactions can take place in aqueous solutions as well in the dry state. If the concentration of ozone is high enough and the organic compound (e.g., an olefin) is reactive enough, the reacting mixture may ignite and burst in flames [169].

In industrial areas with high levels of air pollutants, ozone destroys and embrittles rubber in automobile tires and brake, fuel, and coolant hoses. Rubber formulators have tried to delay this reaction by adding antioxidants (antiozonants) to the rubber compositions. Antiozonants leach from tires and tire dust and contribute to water pollution and fish poisoning. Sometimes antioxidants are added to solid propellant binders for rockets that need to be stored in air for a long time.

In organic chemistry, ozone is used in ozonolysis (ozonation, ozonization) reactions to convert olefins to oxygenated products and to determine the number of double bonds in polymers. Ozonolysis is the cleavage of alkenes or alkynes by reaction with ozone to form organic compounds in which the multiple carbon-carbon bond has been converted to a carbonyl group. The outcome of the reaction depends on the type of multiple bond being oxidized and the workup conditions. Intermediates of such reactions with alkenes are cyclic ozonides formed in a 1,3-dipolar cycloaddition. Alkenes can be oxidized with ozone to form alcohols, aldehydes, ketones, or carboxylic acids. Ozone will bleach many dyes and stains, but without the formation of unwanted chlorinated byproducts like polychlorinated biphenyls (PCBs) or chloroform.

4.1.2 Analysis of Ozone

Analytical tasks in the preparation and handling of ozone include the analysis of liquid and solid ozone mixtures and the detection of gaseous ozone in the air. The analysis of mixtures of liquid and solid ozone with other chemicals must be conducted with physical methods of measurement because the mixtures can often not be vaporized without premature decomposition or even explosions.

4.1.2.1 Analysis of Gaseous Ozone in Air

Because ozone plays an important role in atmospheric chemistry and pollution control, there are many analytical methods for analysis of ozone in air.

For occasional spot checks of ozone concentration in air at the workplace, the easiest method involves using gas detection tubes made from glass tubes that contain an indicator supported on a granular material, which changes color when exposed to ozone. Such tubes are available from Draeger, MSA, Kitagawa, and others. Gas detection tubes are sensitive to as little as 0.05 ppm O₃ and can measure up to 300 ppm O₃ with 10 strokes. Draeger ozone gas detection tubes are available for two ranges of concentration (Table 23).

Table 23: Draeger ozone gas detection tubes.

Tube designation	Concentration range	Draeger part number
Ozone 0.05/b	0.05–1.4 ppm	67 33 181
Ozone 10/a	10–300 ppm	CH 21 001

Data source: [170]

4.1.2.2 Analysis of Gaseous Ozone Grab Samples

The detection and quantification of ozone in air can be done with wet chemical and common gas absorption methods. The bibliography by Thorp [6] contains detailed chapters on the analysis of gaseous ozone.

4.1.2.3 Instrumental Analysis of In-Situ Real-Time Concentration of Gaseous Ozone in Air

Ozonizers are widely used for sterilization of drinking water and for wastewater treatment. To avoid the formation of NO_x, the ozonizers are fed with pure oxygen instead of air. The ozone concentration in the effluent oxygen needs to be monitored to make sure that the ozonizer works properly and to adjust the dilution with air before the gas stream is bubbled through the water that needs to be treated.

Four continuous automatic analyzers for measuring atmospheric levels of ozone were used in a calibration and field study [171]. These were (1) a colorimetric instrument based on the detection of iodine released from neutral potassium iodide reagent,

(2) a coulometric instrument utilizing the polarization current as a measurement of iodine released by ozone in a cell contacted by potassium iodide reagent, (3) a galvanic cell measuring bromine release by ozone, and (4) a UV photometer.

Continuous ozone analyzers are based on chemiluminescent reactions of ozone with dyes (eosin) or electrochemical methods or semiconducting gas sensors based on metal oxides (In_2O_3 , SnO_2). In an evaluation of different sensing techniques, sensors based on indium oxides performed best in detecting ozone [172]. They had the best sensor sensitivity as well as the smallest cross-sensitivities.

Ozone in air will liberate bromine from a bromide solution which is then measured potentiometrically [173]. At an air flow rate of 0.2 L/min the measurable range is 0–1 ppm O_3 for a 1-mV full span recorder.

Ozone concentrations in the atmosphere can be sensed remotely by their IR absorption [174]. The absorptivity at $9.48\text{ }\mu\text{m}$ at 101 kPa is 3.74×10^{-4} ppm m^{-1} .

4.1.2.4 Analysis of Liquid Ozone Mixtures

The analysis of mixtures of liquid or solid ozone with other chemicals must be conducted with physical methods of measurement because the mixtures can often not be vaporized without premature decomposition or even explosions of the ozone contained in the mixture. Because the physical properties of binary ozone mixtures are well known, also at low temperatures where the ozone content remains stable, one can interpolate from measurements of physical properties back to the chemical composition of the mixture. Physical methods are of interest mostly for the analysis of LOZ/LOX mixtures. The physical properties that are easily measured and vary almost linearly with the composition of the mixture are light absorption in the visible range, magnetic susceptibility, and the dielectric constant.

As we review past efforts to dope LOX with ozone to increase its specific impulse and endorse continued efforts with this non-polluting (non-polluting once it is all burned) oxidizer, we wonder how much ozone we have already unwittingly been flying as a contaminant in the millions of tons of LOX that has powered most of our space launches to date. If LOX is produced in a polluted industrial area with a high O_3 content in the atmosphere, where is it going to end up in the air liquefaction plant? In LOX that is intended to be vaporized as breathing oxygen, what is the maximum ozone content allowed?

A crude method of estimating the ozone concentration in LOZ/LOX mixtures is possible based on the knowledge of the phase diagram (the miscibility gap) and by visual observation of the phase separation at $90\text{ K} = -183^\circ\text{C}$. If no darker, heavier phase is formed on cooling, the overall ozone concentration in the mixture is below 24 mass-% O_3 . On the other hand, if there is no lighter, less intensely colored phase floating on the dark liquid ozone, the overall ozone concentration is above 75 mass-% O_3 . Magnetic susceptibility (see below) was a very sensitive criterion of purity of ozone after most of the oxygen had been pumped off.

4.1.2.5 Photometric Methods for Analysis of Liquid Ozone Mixtures

Owing to the intensely blue color of liquid ozone, it can be determined photometrically in mixtures with liquid oxygen by its absorption in the visible range near 600 nm as well as in the UV range at 260 nm. This method is typically used for determining LOZ in LOX in the range 0 to 28 mass-% O_3 . Ozone in solvents (such as CCl_4 , $ClCF_3$, or H_2O) other than LOX can be determined by the same method, but that is less relevant for a rocket propellant application.

As a side note, it is the UV absorption at 260 nm by ozone in the high atmosphere that protects all living beings on Earth from the intense UV radiation of the Sun.

In carrying out photometric measurements at cryogenic temperatures, one must make sure that the cells are constantly cooled to temperatures below 90 K = -183°C and that the cell windows are not covered by frost. One may use double-walled cells like a transparent Dewar flask, or one has to purge the apparatus with cold, dry gas to prevent ambient moisture from entering.

4.1.2.6 Magnetic Susceptibility Methods for Analysis of Liquid Ozone Mixtures

Because LOX is paramagnetic, but LOZ is not, this difference in physical properties can be used for analysis of LOZ/LOX mixtures. The modest diamagnetism of LOZ does not interfere with these measurements. This rapid and easy-to-perform method is best used for the analysis of mixtures containing 72 to 100 mass-% LOZ [163]. The sample to be analyzed is contained in a U-shaped capillary tube and cooled to 78 to 90 K (-195 to -183°C). Initially the tube is carefully leveled and the liquid level recorded. One of the legs of the U tube is surrounded by a powerful permanent magnet. If the magnet is raised, the liquid in one leg of the U tube rises and the amount of rise is proportional to the amount of oxygen in the sample. If the magnet has a flux density of 8000 Gauss, pure oxygen would rise 100 mm. It was claimed that the method is accurate to within $\pm 0.01\%$ absolute.

4.1.2.7 Dielectric Constant Measurements for Analysis of Liquid Ozone Mixtures

The dielectric constant of pure ozone at 77 K = -196°C is 5.45 ± 0.1 . For LOZ/LOX mixtures at 90 K = -183°C the dielectric constant was measured over a wide range of compositions [175]. For instance, at 6 mass-% O_3 , the constant was $\epsilon = 1.595$. This agreed well with measurements by other authors [133].

4.2 Thermal Stability, Decomposition, Radiation Stability of Ozone

Ozone will decompose, sometimes catastrophically, in all physical states, depending on the energy of the stimulus. We are discussing here slow homogeneous decomposition in the gas phase, stationary decomposition flames in the gas phase, explosive

decomposition in the gas phase, and explosions or even detonations in the liquid and solid state. The decomposition reaction

is strongly exothermic and explains the high energy release during ozone explosions (in reversal of its enthalpy of formation, which is positive).

4.2.1 Kinetics of Ozone Decomposition

The ozone decomposition reaction is thought to proceed as a chain reaction as follows:

where M may be a third body that could be another ozone molecule, an inert diluent gas molecule, or the hot wall of the container. There is no evidence for a direct bimolecular reaction of ozone to produce O_2 , nor is there any evidence for important surface effects or energy chains [176]. On the other hand, the results at very fast rates of decomposition indicated an acceleration that can be accounted for in terms of temperature gradients in the system. This region is usually very close to the thermal explosion limit. The values found for the rate constants are (for M equal to O_3) as follows [177]:

$$\begin{aligned} k_1 &= 4.61 \pm 0.25 \times 10^{12} \exp(-24000/RT) \text{ L mol}^{-1} \text{ s}^{-1} \\ k_2 &= 6.00 \pm 0.33 \times 10^7 \exp(+600/RT) \text{ L}^2 \text{ mol}^{-2} \text{ s}^{-1} \\ k_3 &= 2.96 \pm 0.21 \times 10^{10} \exp(-6000/RT) \text{ L mol}^{-1} \text{ s}^{-1} \end{aligned}$$

As with many energy transfer processes, k_1 has an abnormally high preexponential factor, and k_2 has a correspondingly negative energy of activation. It was further inferred that the reaction that produces two O_2 molecules with 99 kcal of excess energy between them does not produce more than one excited electronic state of O_2 and that these hot O_2 molecules are not very efficient in exciting O_3 to decomposition. Reevaluating the constants based on a different enthalpy of formation of atomic oxygen, the numbers (evaluated at 363 K) are as follows [178]:

$$\begin{aligned} k_1 &= 6.8 \times 10^4 \exp(-24890/RT) \text{ mol/L} \\ k_2 &= 2.96 \times 10^7 \exp(+890/RT) \text{ L}^2 \text{ mol}^{-2} \text{ s}^{-1} \\ k_3 &= 3.37 \times 10^{10} \exp(-5700/RT) \text{ L mol}^{-1} \text{ s}^{-1} \end{aligned}$$

Other investigators found similar numbers for the rate constant k_1 , such as [179]

$$k_1 = 4.31 \times 10^{14} \exp(-22.2/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}, \quad 300 \leq T \leq 3000 \text{ K}$$

or [180]

$$k_1 = 1.6 \times 10^{12} \exp(-24300/RT) \text{ L mol}^{-1} \text{ s}^{-1}$$

(at 11–52 mmHg and 388 to 403 K (115–130 °C))

The photolysis of ozone may follow a different pathway than the thermal decomposition.

The slow decomposition of ozone in the gas phase has been studied extensively by kineticists because it is a relatively simple reaction, with no or only a few byproducts, and well suited to demonstrate gas-phase kinetics and fundamental reaction orders. This reaction is merely a limitation in our ability to store and pump ozone as a rocket propellant. A summary of all the kinetic studies on the decomposition of ozone would fill an entire book. In a book on rocket propellants, the only justification for dealing with the kinetics of ozone decomposition would be the promise that it could help us find an inhibitor that would stabilize ozone sufficiently so it could be safely used as a rocket propellant. Such an inhibitor has not been found, and the success of inhibiting the premature decomposition of ozone is as unlikely as trying to stop or slow down the radioactive decay of a radioactive isotope.

4.2.1.1 Thermal Decomposition of Gaseous Ozone

There are hundreds of publications on the slow thermal homogeneous gas-phase decomposition (pyrolysis) of ozone in the dark. Those studies were done mostly in support of atmospheric chemistry and to derive kinetic equations. The storage stability of gaseous ozone in the laboratory closely relates to those studies and will be discussed in Section 4.2.8. Many of those studies were done in the search for additives that might slow down the rate of ozone decomposition. It is impossible to include a complete summary of all publications on the thermal decomposition of ozone in this book. References to a few typical publications may suffice. The slow thermal decomposition of ozone is the slowest of the three basic modes of ozone decomposition: **(1)** slow decomposition in the dark, **(2)** stationary flames, and **(3)** detonation.

The bond dissociation energy of ozone, defined as the energy necessary to break the first bond, is 104.6 kJ/mol (25 kcal/mol), far less than the mean thermochemical value of 299 kJ/mol (71.5 kcal/mol) per bond. See also [181–183].

4.2.1.2 Catalytic Decomposition of Gaseous Ozone

The ozone molecule is very labile, and it does not take much energy stimulation or lowering of the activation energy to decompose it. On the surface of catalysts, the rate of decomposition of ozone is accelerated. Unreacted ozone gas that has passed through drinking water in order to disinfect and sterilize it must be destroyed by catalytic converters before it may be vented above the roof.

Thirty-five materials, including charcoal, metals, and metal oxides, were tested for their catalytic efficiency in decomposing ozone at room temperature [184]. Charcoal and nickel(II) oxide were found to be the best catalysts. A 0.5-in.-thick filter bed of these active materials initially removed 95 and 80%, respectively, of the ozone from a 1 ft³/min air stream containing 250 ppb of ozone. The catalytic efficiency of all the materials tested was found to degrade with time. Operating parameter tests with the charcoal and nickel(II) oxide showed that their efficiencies at a constant flow rate were nearly invariant over input ozone concentrations ranging from 45 ppb to 1.0 ppm and that at a constant input ozone concentration, their efficiencies decreased with an increase in flow rate over the range 0.14–1.17 ft³/min. Palladium-impregnated manganese(IV) oxide is an active ozone decomposition catalyst [185].

Aerosol particulates suspended in the atmosphere may cause ozone decomposition and catalyze interaction of ozone with other atmospheric pollutants. Many of the ozone reactions with organic compounds that are used on a large scale every day in the chemical process industry may be enabled or accelerated by catalysts. The primary method of destroying unwanted ozone (e.g., ozone that has completed drinking water sterilization) before releasing it into the atmosphere is by catalytic decomposition by passing it over a heated catalyst bed. Catalysts might destroy toxic ozone from the ambient air pumped into pressurized cabin passenger aircraft cruising at high altitudes. If ozone were more stable, one might envision monopropellant rocket thrusters with packed catalyst beds operating on gaseous ozone like hydrazine or hydrogen peroxide monopropellant thrusters.

4.2.2 Storage Stability of Ozone

Ozone will decompose slowly if stored as a gas at room temperature. Examples of ozone losses in gas are summarized in Table 24. The source of these data unfortunately does not state the container materials (presumed to be glass) and whether the samples were kept in the dark. The rate of decomposition probably depends on the absence of any catalytic contaminants in the container material. Gaseous ozone would preferably be stored in glass or quartz vessels [186].

The rate of decomposition of gaseous ozone can be slowed down by adsorbing the gas on large-surface-area materials, such as silica gel or glass wool. Aqueous solutions of ozone decompose more slowly in alkaline than in acidic solutions. It has been suggested that even the decomposition of gaseous ozone can be delayed if the walls of the storage containers are coated with strongly alkaline chemicals [188]. The yields and lifetimes of ozone and ozonide produced by the photochemical decomposition of hydrogen peroxide and sodium persulfate in water made alkaline with sodium hydroxide were improved by an increase in sodium hydroxide and oxygen concentration.

Table 24: Decomposition of gaseous ozone during storage.

O ₃ Mol-%	T, K	P, mm Hg	Amount of O ₃ decomposed	Rate of decomposition, %/d
40	296–299	740	4.2% in 7 d	0.6
50	273	766	2.9% in 3 d	0.9
50	296–297	600	4.5% in 5 d	0.9
100	195	754	No noticeable decomposition in 8 d	0.0
100	296	757	0.9% in 1 d	~0.9

Data source: [187]

4.2.3 Stationary Ozone Decomposition Flames

The decomposition reaction of gaseous ozone proceeds via

and is strongly exothermic ($143.17 \pm 0.753 \text{ kJ/mol} = 34.220 \pm 0.180 \text{ kcal/mol}$) at constant pressure $p = \text{const} = 1 \text{ atm}$ and $T_a = 291 \text{ K}$. The flame can be stabilized on a burner if the burner has a properly designed flame holder and if the entrance velocity is sufficiently high to prevent flashback of the flame into the feed system [73, 77, 187, 189]. The flame temperature of pure ozone is appreciably hotter than the temperature of methane-air (2148 K) or carbon monoxide-air (2370 K) flames.

Because only very few species are involved in ozone decomposition flames, this simple reaction constitutes a suitable model reaction to validate flame combustion models. The stability of a steady-state solution of a model for ozone decomposition flames has been investigated for five different cases of ozone flame propagation [190]. The cases chosen were all for $T_0 = 573 \text{ K}$ (300 °C) and at 83 kPa (0.821 atm), so that the experimental data of Hirschfelder, Curtiss, and Campbell could be used to verify the model. The predicted flame speed for an adiabatic flame temperature of 3153 K was 986 cm/s with diffusion and 1560 cm/s without back diffusion.

4.2.3.1 Flammable Range of Ozone Decomposition Flames

Ozone will sustain a decomposition flame over a wide range of pressures and compositions in dilution with inert gases. The range of conditions where ozone decomposition flames propagate and can be stabilized on a burner depends on the ozone content of the gas, operating pressure, preheat temperature of the gas, mode of ignition, and burner diameter. If the flow rate of the gas is too slow, the combustion zone will flash back into the supply lines. If the ozone concentration is at the upper end of the safe range, the combustion could at any time transition into a detonation and destroy the apparatus.

Most ozone generators do not produce ozone concentrations higher than 10 vol-%. In many industrial applications where ozone is used as a reactant and disinfectant, it

would be desirable to use higher concentrations, but they are limited by the explosion potential of gaseous ozone once the concentration exceeds 10 vol-%. Using ozone to sterilize medical equipment at concentrations higher than 10% would entail the same explosion hazard as the medical equipment industry experienced with ethylene oxide, which has caused severe explosions in medical equipment factories.

At atmospheric pressure (298 K at 101 kPa), ozone will sustain a decomposition if initiated by a shock wave as long as the ozone concentration in a mixture with oxygen is above 9.2 mol-% [191]. Thermal ignition with a hot wire or a spark will ignite only above 10 mol-%.

4.2.3.2 Flame Burning Velocity of Ozone Decomposition Flames

Flame Burning Velocity of Decomposition Flames in Pure (Undiluted) Gaseous Ozone

The thermodynamic data for ozone and oxygen are very accurate and formed the basis for calculations of the theoretical flame temperatures and flame speeds of the gaseous ozone flame summarized in Table 25 and 26 from several literature sources [187, 189, 192].

Spectrometric investigations indicate that some of the energy transport in gaseous ozone decomposition flames and detonations occurs through radiative transport. If the radiative energy loss can be quantified, one can use it to correct the measured flame temperature and calculate the adiabatic flame temperature [193, 194]. A kinetic scheme capable of representing both the observed UV quantum yields in pure ozone and the thermal decomposition rates in O_3/O_2 mixtures was designed for the calcu-

lation of temperature-composition histories during photo-initiated ozone explosions [195].

The theoretical equations developed for the prediction of ozone flames at atmospheric pressure [196] were then extended to predict the flame velocities for gaseous ozone flames burning at higher pressures [197] (Table 27).

Table 27: Theoretical decomposition flame velocities in pure (undiluted) ozone.

Data source: [197]

Because the kinetics of decomposing ozone are relatively simple (compared to the combustion of other monopropellants like nitromethane or hydrazine), the ozone decomposition reaction was selected to test the validity of several models for the prediction of laminar flame speeds [198]. Model predictions were compared with available experimental data for ozone decomposition flames, and the agreement was satisfactory.

Species and temperature profiles and the burning velocities were predicted over a range of initial ozone mol fractions of 0.25 to 1.00 [199]. The computed burning ve-

locities were no more than 30% greater than the measurements of Streng and Grosse. Comparison with the computed results of Warnatz showed agreement within $\pm 12\%$, even though they used quite different expressions for some of the kinetic coefficients. Differences are most likely due to different methods to account for atomic oxygen. See also [183].

Figure 18: Decomposition velocities of gaseous ozone/oxygen mixtures. (Reprinted and modified from [187], with permission from Elsevier © 1957, permission conveyed through RightsLink.)

Flame Burning Velocity of Decomposition Flames of Gaseous Ozone/Oxygen

The speed of flame propagation in ozone/oxygen gas decomposition flames in the absence of any fuels increased steeply with increasing ozone concentration, starting at 20 mass-% ozone where a flame can be maintained, progressing through combustion, deflagration, and all the way to detonation. The ranges of reactivity are illustrated in Figure 18.

The theoretical flame speeds of gaseous oxygen/ozone mixtures were calculated using a method similar to that described earlier for pure ozone. The results are summarized in Table 28, and a comparison with experimental values shows moderate agreement between the two sets of data. Table 29 gives the theoretical flame temperatures of ozone/oxygen decomposition flames.

Table 28: Flame speeds of gaseous ozone/oxygen mixtures.

Ozone concentration Mol-%	Calculated		Measured

Data source: [187]

It has been shown that that no steady flame can be produced in concentrated ozone and that detonation would invariably result with ozone/oxygen mixtures above 54 mass-% ozone.

The theory of flame propagation in gaseous ozone/oxygen mixtures was applied to mixtures containing 50–100 mol-% ozone [196, 200]. The formulas were modified to allow for comparatively high concentration of atomic oxygen. The results for $T_0 = 298\text{ K}$ shown in Table 30 were found to be in good agreement with three experimental values. Additional data were calculated for $T_0 = 195\text{ K}$ (dry-ice temperature).

Table 30: Calculated flame velocities and flame temperatures in gaseous ozone/oxygen mixture decomposition flames.

Initial temperature $T_0 = 298\text{ K}$								
Mol fraction ozone	0.25	0.40	0.50	0.60	0.70	0.80	0.90	1.00

^a Calculated by [200] for diffusion coefficient $\delta = 0.94$

^b Calculated from empirical equation found by Streng and Grosse $V_0 = 563 \times \text{mol fraction } \text{O}_3 - 88.8\text{ cm/s}$

^c Measured by Lewis and von Elbe

Data source: [200] and [197]

A calculation method for predicting flame velocities of ozone and ozone/oxygen decomposition flames was developed that included complete multi-component diffusion and heat conduction solving the time-dependent mass and energy conservation equations of a laminar flame [201]. Calculations with simplified transport models were made for comparison. The flame speed could be predicted as a function of the initial $\text{O}_3 : \text{O}_2$ ratio, and it agreed reasonably well with experimental data. See also [202–205].

4.2.3.3 Quenching Diameter of Gaseous Ozone Decomposition Flames

The quenching diameter (“critical diameter”) of flames in a cylinder as a function of pressure (at 298 K) can be expressed by the equation

$$\log d_c = 1.953 - 1.111 \log P$$

where d_c is the quenching diameter in micrometer (μm) and P is the pressure in atm [206]. For example, in a cylinder at 1 atm and 298 K, the quenching diameter is 90 μm ,

the smallest of any gaseous reactant known. The quenching diameter of flames in a cylinder as a function of temperature (at 101 kPa) can be expressed by the equation

$$d_c = 347.5 - 0.864 T$$

where d_c is the quenching diameter in micrometer (μm) and T is the temperature in kelvin.

Table 31 gives an overview of some quenching diameter measurements obtained under different conditions.

Table 31: Quenching diameter of ozone and ozone/oxygen flames.

Ozone concentration Mol-%	Temperature K	Pressure atm	Quenching diameter mm
15	298	1	5.000
25	298	1	1.650
50	298	1	0.390
75	298	1	0.165
100	298	1	0.090

Data source: [206]

For information on the critical diameter of capillary passages through which ozone decomposition may propagate, see also [207].

The minimum gas flow to prevent flashback of an ozone flame is a function of the burner diameter (Table 32).

Table 32: Minimum gas flow or flashback flow at 1 atm and 298 K = 25 °C.

Burner tube internal diameter, cm	Minimum flow, flow rate, cm^3/s
0.065	7
0.1	29
0.2	232
0.3	725
0.6	6090
0.8	14500
1.0	29000
2.0	232000

Data source: [77]

4.2.4 Detonation of Gaseous Ozone

A flame front propagating unimpeded into gaseous ozone or ozone/oxygen mixtures may undergo a deflagration-to-detonation transition (DDT), and the remaining un-

reacted gas detonates. Numerous investigators have measured the critical diameter above which explosions become possible, and the critical quenching diameter in capillary tubes below which an established detonation becomes extinguished and fails to propagate. The critical quenching diameter of pure ozone is the smallest of all known detonable gases and gas mixtures.

When curve fitting the data and expressing the quenching diameter d_c of gaseous ozone/oxygen mixtures as a function of chemical composition, the quenching diameter could be expressed by the following equations:

$$\log d_c = 6.189 - 2.118 \log x \quad \text{at 1 atm and 298 K}$$

$$\log d_c = 6.403 - 2.113 \log x \quad \text{at 1 atm and 195 K}$$

where d_c is the quenching diameter in micrometers (10^{-6} m), and x is the ozone concentration in vol-% O_3 .

Determination of the critical quenching diameter has practical significance insofar in terms of preventing the detonation of gaseous ozone by filling the storage volume with inert, porous particles. The pore size and interstitial spaces of these particles should be on the same order of magnitude as or smaller than the quenching diameter ($\sim 200 \mu\text{m}$). Ozone did not decompose when stored in containers of various materials under test (glass, aluminum, stainless steel) at dry-ice temperature [208].

The detonation velocity of gaseous ozone and ozone/oxygen mixtures are presented in Table 33, where we can compare experimental and theoretical results which agree quite well.

Table 33: Theoretical and experimental detonation velocities of gaseous ozone and gaseous ozone/oxygen mixtures.

Ozone concentration Mol-%	Detonation temperature K	Detonation pressure atm	Detonation velocity ^a m/s	
			Calculated	Measured
100	3340	30.78	1878	1863 $\pm$ 20
75	3110	25.50	1795	1782 $\pm$ 40
50	2645	19.15	1637	1633 $\pm$ 20
25	1705	10.89	1290	—

^a at 298 K = 25 °C and 101 kPa = 1 at, based on data from [209] and [192]

Similar results were reported by others and are summarized in Table 34 and 35.

The effect of diluents and critical ignition energy on the ignition of gaseous ozone in a range of 153 to 326 K (-120 to $+53$ °C) was examined with either spark ignition or thermal ignition on hot surfaces [212]. O_2 , CO_2 , H_2O , and SiF_4 were tested as diluents. The nature of the diluent gas had only a slight effect on the location of the lower limit

Table 34: Calculated and measured detonation velocities of gaseous ozone/oxygen mixtures.

Ozone concentration Mol-%	Initial pressure mm Hg	Detonation velocity m/s		Deviation of measured vs. calculated % relative

of detonability. The autoignition temperatures could be calculated based on the Semenov theory and agreed well with the data measured by Kamenetskaya. Thermal ignition experiments were conducted with gaseous ozone [213].

To test ignition limits, the calculated amount of 100% pure gaseous ozone was introduced into an evacuated cylindrical phosphor bronze vessel, 90 mm in diameter and 180 mm high. The ozone was then diluted with oxygen to the required concentration, and the mixture ignited by a spark from a 4-μF capacitor [214]. Test with sparks from a Tesla coil of considerable higher energy produced practically identical results. When it was found that the explosive limits of gaseous ozone/oxygen mixtures depended on the container material (glass or metal), the investigators assumed that

a chain reaction is sustained and that the wall material might be a chain terminator. However, this interpretation was challenged by others.

Attempts were made to predict the detonability of gases from theoretical considerations, and the reliability of those predictions was tested against experimental data for nitric oxide or ozone. It was predicted that ozone would detonate but nitric oxide would not [215]. Additional information on ozone detonations can be found in the following references: [191, 216–218].

The velocities of steady detonation waves in gaseous ozone were measured over a wide range of conditions in tubes with diameters between 1 and 25.4 mm, at initial pressures between 10.66 and 29.3 kPa (80 and 220 mm Hg), and in mixtures containing from 72.5 to 96.6 vol-% O_3 in oxygen or argon. The experimental velocities, extrapolated to infinite tube diameter, agreed within experimental error with those calculated by the classical theory of Chapman and Jouguet [219, 220].

Experimental and theoretical studies have been conducted on the nature of concentrated ozone decomposition [221]. Ozone with concentrations above 50 vol-% can produce a passivated layer on the surface of stainless steel, which is considerably less active to ozone decomposition. The ozone decomposition rate was strongly dependent on temperature, concentration, and pressure. The activation energy and order of reaction for the decomposition was reaffirmed. N_2 , Ar, and He dilution had no effects on ozone decomposition, while CH_4 and H_2 acted as catalysts, and CO reacted with ozone under room temperature and pressure conditions.

A series of ignition experiments using electric spark ignition was conducted to investigate the explosion hazards of gaseous ozone with concentrations of up to 60 vol-% [222]. The results showed that the lower explosion limit of ozone in oxygen at room temperature and atmospheric pressure was about 10 vol-%. Partial decomposition of ozone in the ignition vessel was observed in a range of 10 to 12 vol-%, and only ozone with a concentration exceeding 12 vol-% could cause an explosive chain decomposition and convert to oxygen completely. The lower explosion limit shifted to higher concentrations with decreasing initial pressures. For instance, at 100 mm Hg the lower limit was 25 vol-% O_3 . The explosion limit sharply increased at a pressure of 100 mm Hg or less. For example, the lower explosion limits at 600, 200, 80, and 20 mm Hg were estimated to be 12, 12.5, 15, and 30 vol-% O_3 , respectively. It seems that carbon dioxide has a weak inhibiting effect on ozone explosions. Adding 70 vol-% carbon dioxide to an ozone/oxygen mixture raised the lower explosion limit from 10 to 12 vol-% O_3 .

The explosion trigger energy (minimum ignition energy) is strongly dependent on ozone concentration and pressure. For example, the minimum trigger energy for 15 vol-% ozone at a pressure of 76 mm Hg (about 220 mJ) was more than 20-fold that at atmospheric pressure (about 10 mJ), and that for 13 vol-% ozone (about 580 mJ) was approximately 30 times higher than that for 20 vol-% (about 20 mJ) at the same pressure of 76 mm Hg [223]. A slight change in ozone concentration resulted in a large

difference in the minimum trigger energy. There was a 16-fold difference in ignition energy between 12.4 and 14.3 vol-% O_3 at a pressure of 200 mm Hg.

The detonation and deflagration properties of ozone/oxygen mixtures of up to 20 vol-% O_3 in oxygen under high pressures of up to 1.0 MPa in a closed cylindrical tube were experimentally investigated [224]. The mixtures were ignited by an electric spark at one end of the tube. Flame propagation properties such as flame velocity and pressure were measured with thermocouples and piezoelectric transducers mounted along the tube. Slow and constant flame propagation profiles were obtained. Figure 19 shows the steady flame velocity as a function of ozone concentration between 14 and 20% O_3 at an initial pressure of 0.1 MPa.

Figure 19: Steady flame velocity of ozone decomposition flames at 0.1 MPa. (Republished and modified from [224], with permission of © 2001 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center, Inc.)

Figure 20 shows the flame speed as a function of pressure for a constant ozone composition. The flame speed increased only moderately when the pressure of a mixture containing 13.4 to 14.3 vol-% ozone was increased from 0.1 to 1 MPa.

The quenching ability of a wire gauze was tested as a flame arrestor. A 20-mesh stainless-steel wire gauze was inserted in the middle of the test section. A 15 vol-% O_3 flame was quenched at atmospheric pressure. However, when the mixture was flowing, the flame was trapped by the gauze and kept burning on the surface of the gauze.

Figure 20: Steady flame velocity of ozone decomposition flames as a function of initial pressure. (Republished and modified from [224], with permission of © 2001 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center, Inc.)

The wire gauze acted as a flame holder. The lower concentration limit for flame propagation was measured under different conditions. Deflagration-to-detonation transition by an electric spark ignition was not achieved under these experimental conditions. In near-limit mixtures, despite slow flame propagation velocity and easy flame quenching properties, direct initiation of detonation by a driver (donor section) detonation of a stoichiometric oxygen-hydrogen mixture was easily achieved at much lower O_3 concentrations than the limit of deflagration. The observed detonation properties, such as wave velocity and pressure, agreed well with Chapman-Jouguet (C-J) calculated values. The detonation velocity (900–1200 m/s) and the pressure ratio of final to initial pressures (5–9.5) were not affected by the initial pressure of the mixtures. Near the detonation limit, typical spinning detonations with oscillatory pressure waves were observed. Figure 21 shows the detonation velocity of an oxygen-hydrogen donor-driven ozone detonation as a function of O_3 concentration. The solid line denotes the theoretical detonation velocity from a C-J calculation. Little change in the detonation velocity with tests at different initial pressures in the target section of the shock tube.

4.2.5 Strand Burning of Liquid or Solid Ozone and Their Mixtures with Oxygen

When taking certain safety precautions, it is possible to burn solid or liquid ozone in thin strands unconfined or confined in capillary tubes. The ignition energy must be kept at a minimum so that it just ignites combustion but does not initiate a detonation. A condensed-phase ozone strand burns like many monopropellants, even in the absence of other fuels. However, if hot spots develop unintentionally, the apparatus may explode.

Calculated theoretical strand burn rates and flame temperatures of ozone combustion are summarized in Table 36.

The burn rate and flame temperature of solid ozone and ozone/oxygen mixtures (with 50 and 75% O_3) are lower than corresponding data in the liquid state. The difference between liquid and solid samples is least with pure ozone. The burn rate is dependent on the sample starting temperature, which is most pronounced with the mixtures and least noticeable with pure ozone.

The strand burning of solid ozone, with or without intermediate formation of a liquid melt layer, has been used as a simple example to test computational models for homogeneous solid propellant (monophasic energetic materials like RDX)

Table 36: Calculated theoretical strand burn rates and flame temperatures of combustion of ozone and ozone/oxygen mixtures.

Physical state	Starting conditions		Ozone concentration mol-%	Burn rate cm/s	Flame temperature K
	Pressure atm	Temperature K

Based on data from [225] and [226]

burning. Modeling the burning of solid ozone was much simpler than modeling the burning of RDX. One process modeled was a gas/surface reaction. A detailed analysis was performed on the reaction mechanisms at play in the ozone flame and how they are affected by the heterogeneous reaction [227–229].

The detonation of solid ozone was simulated using a reactive empirical bond order (REBO) potential formality, which described the gas-phase properties of isolated reactant and product molecules and high-density phases generated under shock compression [230]. The model described an ozone molecular solid with the density and velocity of sound within physical norms. The detonation characteristics depended on crystallographic orientation of the crystals.

Even tiny, nanoscale voids and cracks, imperfections in the crystal lattice, can aggravate the shock sensitivity of solid ozone. The initiation characteristics of the model were dependent on the crack width, suggesting that there was also a similar geometry-dependent effect in detonation propagation [231]. A two-dimensional simulation was developed for the detonation of a model crystal consisting of solid ozone [232]. The presence of nanoscale voids lowered the initiation threshold of detonation.

4.2.6 Detonation of Liquid Ozone and Liquid Ozone/Liquid Oxygen Mixtures

4.2.6.1 Detonation of Liquid Ozone

An attempt was made to explain the liquid-phase detonation behavior of liquid ozone by establishing a chain reaction of kinetic events [233]. Measured critical diameters for the propagation of ozone detonations in capillary tubes agreed with those predicted by Khariton's theory about the critical diameter of solid explosives.

4.2.6.2 Detonation of Liquid Ozone/Liquid Oxygen Mixtures

If one plots the temperature required for thermal initiation of LOZ/LOX (15 to 90% O₃) detonations by flash heating, the minimum required energy is an exponential function of the ozone concentration c [234, 235].

A solution of ozone in LOX will not detonate if the initiation energy E is smaller than

$$E_{\min} = 186e^{-\frac{c}{6.9}}$$

where c is the ozone concentration in mass-% and E is the energy in cal. The mechanical shock sensitivity of liquid ozone can be determined using either the drop weight sensitivity test method or the adiabatic compression sensitivity method. The pressure increase that leads to the detonation of LOZ/LOX mixtures can be expressed as an exponential equation of the ozone concentration c and decreases with increasing ozone concentrations [236, 237]:

$$P_{\text{ref}} = 173e^{-0.0382 \times c_{\text{O}_3}}$$

where c is the ozone concentration in mass-% and P is the pressure in atm. The shock sensitivity of these mixtures seems to be proportional to the energy required for thermal initiation. Only mixtures with less than 29.5 mass-% and more than 68.5 mass-% ozone were investigated because mixtures in the interim range would separate into two phases. Glycerin trinitrate, known to be very shock sensitive, was tested in the same apparatus for comparison. It exploded when suddenly compressed from 1 to 96 atm. There appears to be some sort of correlation between the shock (adiabatic compression) and thermal initiation of LOZ/LOX mixtures. The test series used only mixtures with less than 29.5 and more than 68.5 mass-% O₃, because intermediate mixtures have a tendency to separate into two immiscible phases. Glycerin trinitrate (nitroglycerin) was tested for comparison in the same adiabatic compression sensitivity apparatus. It exploded when suddenly compressed from 1 to 96 atm. The experiments from which the two preceding equations were derived were conducted in an apparatus whose basic element was an explosion vessel, a tube 20 mm in diameter and 400 mm in length. A shock tube (diameter 20 mm, length 1080 mm), divided into two unequal sections by a rupture diaphragm, was inserted in the enlarged upper section of the vessel. The results obtained showed that ozone/oxygen solutions possess a very high sensitivity to pressure pulses. The dilution of liquid ozone with oxygen

led to a sharp decrease in the pressure pulse necessary to excite an explosion in the solution.

One of the reports stated that “Solid ozone with solid carbon dioxide, nitrous oxide, and argon present has the same impact sensitivity as solid ozone alone. The use of solid ozone is to be avoided” [238].

The handling of liquid ozone and ozone/oxygen mixtures presents a very difficult challenge because one must maintain a narrow range of temperatures. If the temperature of homogeneous mixtures drops below a critical temperature, phase separation causes an ozone-rich layer to precipitate which has been blamed for many of the explosions observed with ozone/oxygen mixtures [239]. Such mixtures are sensitive to initiation by mechanical shock, flames, or electric sparks. Liquid oxygen at its natural boiling point (90 K = -183°C) dissolves 17.6 mol-% ozone. If the ozone concentration in the mixture exceeds this number, for instance at 18.6 mol-% O_3 , an electric spark causes a weak explosion. Above 21 mol-% it causes a violent detonation. If the ozone content exceeds 23 mol-%, the mixtures begin to become sensitive to shock. Two-phase mixtures with even higher ozone concentrations explode regardless of the type of initiation stimulus (often unintentionally). Table 37 shows that the explosive limit of LOZ/LOX mixtures decreased instead of widened with decreasing temperatures, as one might expect. This was caused by the phase separation happening as the mixture cooled off. Only at very low temperatures does one notice a stabilizing effect from lowering the temperature.

Table 37: Explosion limits of liquid ozone/oxygen mixtures.

Temperature		Composition	
K	$^{\circ}\text{C}$	Mol-% ozone	Mass % ozone
90	-183	17.6	24.3
89	-184	15.0	20.9
87	-186	10.8	15.4
85	-188	8.8	12.6
83	-190	7.7	11.1
81	-192	7.0	10.1
79	-194	6.8	9.9
77	-196	6.9	10.0

Based on data from [239].

The limits of detonability and detonation velocity of LOX/LOZ solutions using a spark ignition were determined at temperatures above the boiling point of LOX [211]. To obtain homogeneous mixtures at temperatures above the boiling point of LOX, samples were held in pressurized vessels. Mixtures containing less than 50 mass-% ozone could be made to detonate by a weak spark.

If a charge of 100% liquid ozone was used as a booster charge, explosions were possible in mixtures containing less than 50 mass-% O_3 . In a mixture containing 35 mass-% O_3 , this mode of initiation triggered only a relatively slow decomposition reaction. The results are summarized in Table 38.

Table 38: Detonation properties of LOZ/LOX mixtures.

Ozone concentration Mass-%	Capillary diameter mm	Initial pressure atm	Ignition method ^a	Tube material	Type of observed detonation	Velocity of detonation m/s

^a Method of initiation: A = direct electrical spark; B = initiation by a booster charge of 100% ozone
Based on data from [211]

Sometimes a weakly luminescent decomposition front was observed propagating into the mixture, which, after traveling halfway down the tube, suddenly transitioned into an explosion (detonation?) front. The data for 100% ozone in the preceding table agreed well with calculated theoretical data reported earlier [209] ($v = 5070$ m/s, $T = 3140$ K, $P_{\text{expl.}} = 4 \times 10^4$ atm; start conditions: 90 K, 1 atm).

The detonability of LOZ/LOX mixtures was determined in tubes of various diameters and different containment materials [240]. Such data are of practical value if one wants to prevent ozone detonations from propagating from the rocket combustion chamber into the injectors, the feed system, or even the oxidizer supply tank. Samples containing 100, 49, 40 or 30% ozone in LOZ/LOX were confined in steel or lead pipes that were 40 cm long, 12 mm ($\frac{1}{2}$ in.) outer diameter (OD), and having a wall thickness

of 0.8 mm (1/32 in.) and initiated either by an electric spark or by a booster charge of 100% ozone. The detonation of 100% LOZ disintegrated the tubes into tiny splinters. In addition, 49- and 40-% LOZ resulted in coarser splinters and required a LOZ booster, while 30% LOZ was not detonable, not even when a booster charge of 100% LOZ was detonated next to it.

An explosion may transfer from a detonation of gaseous ozone/oxygen mixtures to initiate a detonation of a liquid ozone/oxygen solution [241].

4.2.7 Slow Gas-Phase Decomposition of Ozone

There are thousands of publications on gas-phase decomposition, mostly on photolysis under the conditions of the ozone layer in Earth's upper atmosphere. Most of these operate at very low pressures and relate only remotely to the decomposition of gaseous ozone as it is encountered in a laboratory while preparing ozone for a rocket experiment. The decomposition of ozone as a source of singlet atomic oxygen would be of interest for chemical lasers like COIL, where current technology creates atomic oxygen by the reaction of alkaline hydrogen peroxide with chlorine. If ozone could be brought safely on board, the complicated and messy caustic hydrogen peroxide/hypochlorite combination would no longer be needed.

Publications referenced in this section are limited to those operating at atmospheric pressure and with only minimal dilution by inert gases.

4.2.8 Stabilization and Desensitization of Ozone

While stabilizers have been found for high-concentration hydrogen peroxide as a rocket propellant and dextrin has been used as a desensitizer for lead azide, no stabilizers or desensitizers have been found for ozone. Many patents have been filed, but they must be treated with caution and skepticism. Perfluoroethylamine in amounts of 0.5–15% was claimed to reduce the sensitivity of liquid ozone [242].

The detonability of thin layers of frozen ozone depends on the thickness of the layer deposited. Below a certain thickness (<1 mm) the layer will no longer detonate. Amorphous (as opposed to crystallized) solid ozone in thin layers is much less sensitive than bulk frozen ozone prepared by conventional methods [243]. Amorphous samples of solid ozone that formed at temperatures below 20 K were stable to laser irradiation.

The search for inert solvents capable of separating ozone from a process stream and storing it as a solution in a safe manner has been expanded to halocarbons, mostly of the Freon family [244]. An alternate method to dissolving it in inert solvents is to adsorb ozone from a process stream that contains only 8–9 mass-% ozone onto a silica gel in a cold trap. Ozone can be safely stored in this adsorbed state and desorbed in pure form on an as-needed basis. Until 1960, carbon tetrachloride was the only solvent known to be inert toward ozone. However, the ozone solubility coefficient in CCl_4 was relatively low (4.6 at 261 K = -12°C). Freons have solubility coefficients for ozone at

158 K (–115 °C) that are several orders of magnitude better than those of CCl_4 , on the order of 1500–3500. Ozone can be separated from the process gas at the ozonizer outlet by dissolving it in Freon, whereas unreacted oxygen does not dissolve. A trace of free fluorine in Freons has a stabilizing effect on the ozone. The best stabilizer and solvent for liquid ozone is Freon 14, CF_4 . The best stabilizer and solvent for gaseous ozone is Freon 22, CHClF_2 . Neither complexes nor solvates are formed when ozone dissolves in Freons. The concentration of ozone in Freon-ozone mixtures can reach 50%. Solutions of 10% ozone in Freon 12 at 195 K (–78 °C) are completely safe [245]. See also [246].

4.2.8.1 Photolysis of Gaseous Ozone

Not only does ozone form from oxygen under the influence of UV light, but UV photolysis also effects the decomposition of liquid or gaseous ozone [247, 248]. The quantum yield during the photochemical decomposition of liquid ozone at 90 K (–183 °C) is on the order of 2.0. In the ozone layer on top of the atmosphere, a dynamic equilibrium concentration of ozone is maintained (unless “civilized” inhabitants of Earth release ozone-destroying chemicals from their refrigerators and air conditioning units) where ozone is simultaneously formed by the photolysis of oxygen and ozone is destroyed by UV radiation. There are so many publications on the photolysis of ozone under a wide range of atmospheric conditions and in the absence or presence of artificial and naturally occurring halogen compounds that we’ll not attempt to reference any of those here. Suffice it to say that if ozone is ever used as a rocket propellant, it should be kept in the dark. A flash from a strobe or a laser pulse could be used to initiate the decomposition or combustion of ozone and ozone-fuel mixtures in a controlled way.

Light emitted from decomposing ozone may cause adjacent non-decomposed ozone to be photolyzed, thereby propagating the decomposition front in a flame or a detonation at much higher speed than would be expected by traditional theoretical flame velocity calculations.

4.2.9 Radiolysis of Ozone

The same mechanisms that cause the formation of ozone by the radiolysis of oxygen will also lead to the destruction of ozone by radiolysis. Depending on the concentration of oxygen and the intensity of hard radiation, there is a dynamic equilibrium concentration of ozone in irradiated oxygen, like the effect of UV photolysis. Ozone can be smelled in the proximity of radioactive materials in air. The decomposition of ozone by ionizing radiation has been explained by a negative ion-chain mechanism [249]. The γ -irradiation of liquid or solid oxygen is one method for producing ozone, but the ozone yield is limited by the reverse reaction [60, 61].

5 Construction Materials for Handling Ozone

The main concern in selecting construction materials that come in contact with ozone during ozone preparation, concentration, and storage is the inadvertent catalysis of ozone decomposition that can lead to explosions and detonations. Many metals become passivated by the formation of a thin oxide layer once they are in contact with ozone, but some oxides are just as good catalysts as the bare metal itself. Only very few metals are suitable for ozone equipment. Like precautions taken in the first use of new equipment with fluorine, it is best to passivate the equipment slowly by starting out with inert gas and gradually increasing the ozone concentration to the level the system will be exposed to during its nominal operation. For liquid ozone solutions in liquid oxygen, one starts with equipment that is already qualified for LOX and subjects the list of materials to a secondary screening to see if some materials in contact with ozone have to be replaced before the apparatus can be used.

Referring to the literature, the following metals are supposed to be suitable for handling of liquid ozone: aluminum 2S, 3S, 24S, 52S, and 61S; CRES 302, 304, 316, 410, and 416; and titanium and Stellite [18]. It is known that titanium in liquid oxygen is sensitive to shock and shear and the same problem would be encountered with liquid ozone and titanium.

Few elastomers are compatible with ozone. Rubber (latex rubber, ethylene-propylene-terpolymer (EPT) polymers) becomes rapidly embrittled by ozone, and even a low ozone concentration in air (city smog, high-altitude airplanes) will accelerate rubber deterioration. Perfluorinated and perhalogenated polymers are suitable as flexible hoses and gaskets for ozone systems; this includes polytetrafluoroethylene (PTFE), polychlorotrifluoroethylene (PCTFE), and polyvinylchloride (PVC).

6 Toxic Properties of Ozone

Many publications prior to 1958 contradicted each other about the odor and toxicity of ozone at various concentrations [250, 251]. The possible sources of these contradictions were inaccurate methods of analysis used for transient ozone concentrations and a lack of documentation about the quality of the gas (mixture) used for the production of ozone. The purity of the product differs substantially depending on whether pure oxygen or air was used as the starting reactant. Ozone made by ozonization of air contains a very high concentration of dinitrogen pentoxide, which is more toxic than ozone, and its toxicity rivals that of phosgene [252]. See also [253].

The Committee on Toxicology of the US National Academy of Sciences issued a report on emergency and continuous exposure limits for selected airborne contaminants. The report contains a seven-page summary of ozone toxicity and considerations for setting safe limits of ozone concentrations in ambient air [254].

6.1 Inhalation Toxicity of Ozone

The main concern about ozone toxicity is the lifelong exposure of populations in urban areas due to smog formation. Ozone is not the only irritant in these situations; nitrogen oxides, acetyl peroxide, peroxyacetic acid, and many others contribute to lung problems. It would be difficult to single out ozone as the main irritant and health hazard. The olfactory threshold of ozone is 0.05 ppm by volume. Airplanes flying at high altitudes may contain ozone at up to 0.5 ppm in the cabin. For a long time it was assumed that ozone monitors and alarm systems in ozone-handling laboratories were unnecessary because the odor provided ample warning before dangerous concentrations were reached. This position changed in 1979, when the Threshold Limit Value-Time Weighted Average (TLV-TWA) was again lowered, this time to 0.1 ppm.

A volunteer physiologist who inhaled 8 ppm ozone for 1 h suffered significant lung damage, and his respiratory capacity was reduced by 50%. Even concentrations below 8 ppm and exposures lasting less than 1 h can cause swelling of the mucous membranes and lung tissue.

Figure 22 shows the safe limits and observed symptoms in a concentration-time diagram.

Up to 4 ppm and for exposures not exceeding 100 h, one can assume a non-symptomatic range within which one does not observe permanent adverse effects.

In animal tests, exposure of rats to 2.4 ppm ozone caused pulmonary edema and hemorrhage [255]. After breathing in this atmosphere for 32 h, some of the animals ac-

Figure 22: Tolerance and toxicity limits of ozone inhalation in humans. (From [7].)

climatized and suffered no additional effects. In a group of 102 mice exposed to 2 ppm ozone for 24 h, the fatality rate was 20%. The LC 50 after a 4-h exposure was 3.6 to 4.1 ppm for male mice, 3.6 to 6.4 ppm for male rats, and 9.1 to 12.1 ppm for hamsters.

Repeated exposure of rats to 2 ppm ozone for 3 h resulted in rapid (within 3 h) and persistent (up to 72 h) histological changes in the bronchiolar epithelium, including hypercellularity, loss of cilia, and necrotizing bronchiolitis [256].

The American Conference of Governmental Industrial Hygienists (ACGIH) recommendation for inhalation TLV-TWA for ozone in the US was 0.1 ppm in 2010. National Institute for Occupational Safety and Health (NIOSH) recommendations for TLV-TWA (2013) were 0.1 ppm (0.0196 mg/m³) with a **ceiling** notation. The immediately dangerous to life or health (IDLH) concentration was given as 5 ppm, which appears to be quite conservative considering that human volunteers have survived 8 ppm exposure for 1 h (although with significant lung damage). It was recommended to keep the TLV-TWA for humans for the 8-h workday below 0.1 ppm.

7 Handling of Ozone and Ozone/Oxygen Mixtures

Liquid oxygen containing up to 10 mass-% liquid ozone can be handled using essentially the same precautions as for liquid oxygen itself, except for precautions to prevent inadvertent inhalation of boiloff gases vented to the atmosphere. A previous chapter (Section 4.2.6.2) summarized in detail the hazards resulting from the buildup of ozone in residue if oxygen was allowed to evaporate from LOZ/LOX mixtures. To prevent the accumulation of ozone and eventual phase separation of a mixture, either the mixtures must always be cooled externally with liquid nitrogen or the LOX boiloff must be compensated by adding fresh LOX [257]. Storage of LOZ/LOX solutions under pressure narrows the miscibility gap and allows the storage of solutions containing more than 24 mass-% O₃ [258].

Even an experienced experimenter using the proper equipment will occasionally encounter unexpected ozone explosions. Adequate precautions would include bullet-proof plastic shielding and remote manipulation apparatus, like that used for radioactive substances. The various parts of an ozone production and liquefaction apparatus should be separated from each other by blast shields, such that an accidental detonation originating in one part of the system cannot destroy adjacent parts of the system. Detailed instructions for handling liquid ozone can be found in [259, 260].

7.1 Storage of Ozone and Ozone/Oxygen Mixtures

Ozone and ozone/oxygen mixtures can be stored indefinitely at liquid nitrogen temperatures.

It has been suggested that gaseous ozone can be stored safely in cylinders filled with small alumina beads such that the interstitial space is below the critical diameter for ozone detonation propagation [246].

7.2 Transfer of Ozone and Ozone/Oxygen Mixtures

When transferring LOZ/LOX mixtures from one container to another, the receiving vessel and the transfer tubing must be precooled with liquid nitrogen or LOX to prevent changes in the ozone concentration as a result of preferential evaporation of LOX from the mixture. One method would be to immerse the entire apparatus in a bath of liquid nitrogen [240, 261]. Pressurized transfer would best use helium as the pressurant gas.

7.3 Neutralization of Ozone in Boiloff from Storage Tanks

Because the vapor pressure of ozone (<1 mm Hg at $90\text{ K} = -183^\circ\text{C}$) at the storage temperature of liquid oxygen (or liquid nitrogen) (<30 mass-% O_3 in the liquid phase) is very low, the boiloff gases in the storage area contain only a small ozone concentration. This is enough to be irritating, but with proper ventilation this gas would readily disperse in air. If the storage area is not adequately ventilated, the ozone concentration in the room air can reach dangerously toxic or even explosive levels.

It has been proposed to remove small ozone contamination from LOZ/LOX boiloff by passing the gases through a catalyst bed containing manganese(IV) dioxide (Section 4.2.1.2). Manganese oxide acts as a catalyst that will cause ozone to decompose to oxygen. One must be careful that none of the catalyst fines can migrate upstream to the storage container. This method is limited to LOZ/LOX mixtures with less than 30% LOZ, because at higher concentrations the boiloff vapors might reach the explosive limit and the catalyst would trigger an explosion that might propagate upstream to the storage vessel. Finely divided manganese(IV) dioxide is also recommended as a filling for gas masks to protect personnel working in areas with high ozone concentrations. Tests of ozone gas masks were conducted at the Armour Research Foundation at the Illinois Institute of Technology, Chicago, Illinois. The filters and the housing may not contain any gaskets made of rubber or other flammable materials.

Excess ozone that has passed through water treatment plants unreacted must be destroyed before the gases are allowed to vent to the atmosphere. In the water treatment industry, this is done by passing the gases over heated catalyst beds.

Liquid ozone is almost completely stable when kept cold below $161\text{ K} = -112^\circ\text{C}$ [186]. The rate of decomposition in a range of 113 to 161 K (-160 to -112°C) is 0.01 to 0.02% within 24 h . Many materials have been tested for compatibility with ozone, but often the degree of dispersion (particle size of powders) was not reported. Aluminum oxide, manganese(IV) dioxide, and lithium peroxide caused rapid decompo-

sition of gaseous ozone at room temperature, while nickel sponge and activated charcoal caused explosions.

7.4 Lessons Learned in Handling Ozone

Organizations that developed a significant amount of experience in the proper handling of ozone ultimately drew the following conclusions: “It has been the experience of the staff of Armour Research Foundation that highly concentrated ozone, as either a gas or a liquid, can be produced and handled in pilot plant quantities with care and without mishap” and “100% liquid ozone and all liquid ozone/oxygen mixtures, if properly prepared and very carefully handled, are relatively stable” [19, 262].

NASA Lewis Research Center conducted rocket engine tests with LOZ/LOX mixtures as oxidizer in combination with gaseous hydrogen as fuel. During these tests the agency gained substantial and well-documented experience in the handling of LOZ/LOX mixtures at rocket test sites. The experimenters concluded that LOZ/LOX mixtures with up to 30 mass-% O_3 can be handled safely as long as all necessary safety precautions are observed [240, 263]. The handling of more concentrated mixtures is more problematic and was beyond the recommended practice.

7.5 Accident History of Ozone

A paper by Miller [240] contains some impressive images of the damage caused by ozone explosions in rocket test facilities.

8 Ozone Mixtures with Other Oxidizers (Besides Oxygen)

Besides the thoroughly studied LOZ/LOX mixtures, a few more mixtures of LOZ with other oxidizers are of potential interest as rocket propellants. In all these cases the other oxidizer acts as a diluent and reduces the explosive hazards of pure ozone.

For instance, the physical properties of mixtures of ozone/fluorine/oxygen and ozone/fluorine, which represent very energetic oxidizers, have been investigated [264]. It is important to learn that fluorine and ozone, as well as fluorine and oxygen, are miscible in a temperature range from 74 to 79 K in all ratios. This represents a difference from the ozone/oxygen system, which has a well-known miscibility gap that reappears in the ternary diagram of Figure 23. At 77.5 K only mixtures containing less than 10 or more than 89 mass-% ozone are homogeneous solutions. The miscibility gap can be narrowed by the addition of fluorine. Most mixtures with more than 50 mass-% fluorine are homogeneous liquids. In Figure 23, the solid dots indicate homogeneous solutions, and the plus signs indicate the two-phase region.

Figure 23: Phase diagram of ternary system $O_2/O_3/F_2$ at 77 K. (Republished and modified from [264], with permission of © 1962 American Institute of Physics; permission conveyed through Copyright Clearance Center Inc.)

The solid line is the approximate miscibility boundary, but its exact location is not known in the area where the line becomes a dashed line.

Fluorine was added to LOZ/LOX mixtures as a means to prevent a dangerous phase separation and to completely solubilize O_3/O_2 solutions [265–267]. Adiabatic U-tube shock tube tests and critical diameters were determined for homogeneous solutions. These data were then used to determine the maximum concentration of ozone that could be safely handled in flow tests. It was concluded that a solution of ozone, oxygen, and fluorine containing about 30 mass-% ozone and at least 14% fluorine, when handled under carefully controlled conditions, should be a feasible rocket-propellant oxidizer.

Other diluents for ozone that have been tested include nitrogen and carbon monoxide [72]. Despite the similarities of CO and N_2 with respect to their physical properties, they show unexpected solubility behavior in liquid ozone. CO is miscible in all proportions at 77.4 K with liquid O_3 , while N_2 in O_3 and vice versa show very limited solubility. A preliminary ternary composition diagram of the system liquid $O_2/O_3/N_2$ at 77.4 K was given as an example.

Perchlorate Oxidizers

1 Perchlorates in General

Perchlorates are the salts of perchloric acid with metal cations or other nonmetallic cations. Perchlorates are used in numerous industrial applications such as explosives, pyrotechnics, and rocket propellants. The most important perchlorate is ammonium perchlorate (AP), which is the preferred solid propellant oxidizer. With an oxygen balance of +34.04% AP is at the top of the list when comparing solid propellant oxidizers based on their available oxygen content. The second-most important perchlorate is potassium perchlorate, which is used in many igniters and other pyrotechnic formulations due to its thermal stability, which is better than that of AP. Sodium perchlorate is an intermediate in the production of AP. Therefore, its properties are well-known. Lithium perchlorate is often used in mixtures with other perchlorates to improve their properties. Of all the alkali metal perchlorates, lithium perchlorate, LiClO_4 has the highest oxygen content. Metal perchlorates are not used as rocket propellants because the metal oxides formed as a result of combustion add to the non-condensables in the exhaust and result in poor rocket performance. Alkali metal perchlorates are used mostly in pyrotechnic igniter mixtures and in airbag gas generants. This book contains short sections on alkali metal chlorates and perchlorates in Section 11 and earth alkaline metal perchlorates in Section 12. Properties of metal perchlorates have already been sufficiently summarized in other publications such as [1–6].

The 1969 Pearson summary in *Oxidation and Combustion Reviews* was preceded by an earlier version published as a government report and as such is available in the public domain [7]. The first edition of the Schumacher book was even translated into Russian in 1963.

Perchloric acid is of interest for the synthesis of various other perchlorates that are useful as propellant ingredients. Perchloric acid by itself is not used as a rocket propellant, however, its decomposition kinetics have been studied extensively because they play a role in the decomposition and combustion of some perchlorate oxidizers, predominantly that of AP. A section on perchloric acid decomposition is available in the 1968 and 1969 Pearson books and, while we have not devoted an entire section in this book to the decomposition of perchloric acid, a few supplementary references will be provided later in this.

1.1 Environmental Effects of Perchlorates

Perchlorate ions are quite persistent in the environment and perchlorates from AP production wastes and accidental spills have been found to leach into aquifers and drinking water supplies. AP waste streams are generated when cleaning out mixing and

casting equipment where composite propellants have been mixed, cast, and cured. AP waste streams are also generated during the demilitarization of AP-based solid propellants. Careless spillage of perchlorates during decades of propellant processing before its toxic properties were better understood has caused detectable amounts of perchlorates to contaminate some aquifers and drinking water supplies. The environmental effects of perchlorates are discussed in detail in Section 8 of this book.

1.2 Natural Occurrence of Perchlorates

The possibility of naturally occurring perchlorate has only recently received significant attention. In the wake of discovering perchlorate ions in the soil of polar regions on Mars, chemists began to take a closer look at the natural occurrence of perchlorates on Earth and began to realize that solar system-wide perchlorate occurrence is more common than initially assumed. The Phoenix Mars Lander performed aqueous chemical analyses of Martian soil scooped from the northern plains of the *Vastitas Borealis*. The solutions contained ~10 mM of dissolved salts with 0.4 to 0.6 mass-% perchlorates leached from each sample [8]. The remaining anions included small concentrations of chloride, bicarbonate, and sulfate. The strong signal of perchlorate ion overwhelmed the selective ion electrode detector where one would have expected nitrate ion. Saturated solutions of perchlorate salts in water may exist in underground pockets of brine on Mars. These solutions have very low freezing points and very low vapor pressure, such that their existence at certain depths below the surface or even at the surface is possible. It has been speculated that perchlorate ions might be part of a life-supporting extraterrestrial biologic cycle if there are bugs that can thrive on it [9]. If bulk deposits of perchlorates can be found on Mars as mineral deposits, they might be mined and used as rocket propellants for *in-situ* resource utilization (ISRU).

The formation and decomposition of perchlorates have been studied in simulated extraterrestrial ices in laboratory apparatus on Earth. Carbon dioxide-rich chloride-bearing ices were exposed to energetic electrons in laboratory simulation experiments to investigate the formation of chlorine oxides (Cl_xO_y) in the condensed phase on Mars [10]. The radiolysis-induced synthesis of chlorine oxides (Cl_xO_y) was monitored online and *in-situ* via infrared (IR) spectroscopy and quadrupole mass spectrometry (QMS). Three discrete chlorine oxides were identified: chlorine dioxide (OClO), dichlorine monoxide (ClOCl), and chloryl chloride (ClClO_2). Higher irradiation doses supported the facile production of ClO_3^- and ClO_2^- bearing higher chlorine oxides. These can lead to the formation of perchlorates as found on Mars.

Samples of Martian soil scooped from aeolian deposits in Gale Crater and pyrolyzed produced mono-, di-, and tri-chloromethane and oxygen, as identified by evolved gas and gas chromatograph-mass spectrometer analysis equipment on board the Mars Science Laboratory Rover, where the source of the carbon is still in dispute [11]. The temperature at which the first oxygen was observed was similar

to where one would expect it if the soil sample had contained hydrated calcium perchlorate $\text{Ca}(\text{ClO}_4)_2 \cdot n\text{H}_2\text{O}$.

Samples of Martian soil heated to $\sim 1108\text{ K}$ ($\sim 835^\circ\text{C}$) under helium flow released H_2O , SO_2 , CO_2 , and O_2 , where evolved O_2 was coincident with the release of Cl_2 . This suggests that oxygen is produced from the thermal decomposition of an oxygen-chlorine compound [12].

Traces of perchlorates were found in ice and water samples that were collected at remote, pristine locations on Earth where there was very little chance of industrial pollution [13]. Relying primarily on domestic, agricultural, and recreational wells, 326 groundwater samples from across the coterminous United States (US) were sampled and analyzed. Care was taken to avoid known sites of perchlorate use or release, as documented by the Environmental Protection Agency (EPA) in the US. Using IC-ESI-MS and a ClO_4^- internal standard, a method detection limit (MDL) of 40 ng/L perchlorates and a minimum reporting level (MRL) of 120 ng/L was achieved. Of the 326 samples, 147 (45%) were below the MDL and 42 (13%) were between the MDL and MRL. Of the 137 samples that could be quantified, most (109 samples) contained $<1000\text{ ng/L}$ perchlorate. The remaining 28 samples contained between 1000 to 10400 ng/L. It was concluded that perchlorates occur naturally in many groundwaters, but the unusually high perchlorate concentrations ($>10000\text{ ng/L}$) previously reported for the west-central Texas area even in the absence of industrial activity appear to be anomalous. Perchlorate concentrations were positively correlated with nitrate levels ($P < 0.001$) but not with chloride concentrations. A better understanding of the role of atmospheric processes in the formation or transport of perchlorates is needed. Gradually the realization began to emerge that perchlorate ion is more ubiquitous in natural unpolluted environments than earlier generations were aware of [14].

One of the suspect sources of perchlorates in agricultural areas is nitrate fertilizer imported from Chile. Imports of Chilean nitrate fertilizer, which contain perchlorate as a natural component, peaked around 1920 and have dropped significantly since the 1960s. The total amount of Chilean nitrate fertilizer imported into the US between 1930 and 1993 was estimated as being $2.4 \times 10^{10}\text{ kg}$. Assuming an average perchlorate content of approximately 0.2%, the total amount of perchlorates imported over this time was approximately $4.8 \times 10^7\text{ kg}$. Much of that still remains in the soil and some of it has found its way into agricultural products and groundwater. Although the use of Chilean nitrate fertilizer has decreased since its peak in the 1920s, the current amounts of Chilean nitrate fertilizer products being shipped and used in the US are still substantial. According to the Foreign Trade Division, US Census Bureau, the amount of sodium nitrate imported from Chile into US ports in 2001 was 88150 metric tons. Chilean sodium nitrate fertilizers marketed in the US until at least the year 2000 contained about 1–2 mg perchlorate / g fertilizer. Changes made subsequently to the principal manufacturer's refining process have intentionally lowered the perchlorate concentration to less than 0.1 mg/g.

2 Ammonium Perchlorate Production

Beyond any doubt, AP is currently the most important solid rocket propellant oxidizer. Accordingly, this chapter on AP spans several hundred pages.

Ammonium perchlorate, also known as AP, perchloric acid ammoniate, NH_4ClO_4 , and CAS RN [7790-98-9], forms colorless crystals which are not as hygroscopic as ammonium nitrate (AN) or ammonium dinitramide (ADN). AP undergoes a reversible phase change from orthorhombic to cubic crystal structure when it warms from below 513 (240 °C) to above 523 K (250 °C) (see Section 3.1.2). As a solid propellant oxidizer, AP is a topic of much interest in publications, more so than any other solid rocket propellant ingredient. Consequently, trying to assemble and systematically reference this large amount of literature in this chapter of this book has been extremely difficult. In spite of this challenge, we have assembled a chapter that is more complete and more up-to-date than any other publication currently available. Many references had to be omitted because they were either too old or they duplicated work already published by other investigators. Moreover, some publications were written in obscure languages that were difficult to translate.

There are several good summaries on the physical and chemical properties of AP in available literature. A very comprehensive summary containing 320 references is provided by Hall and Pearson [15]. This was supplemented by a publication covering literature published in the subsequent 18 months published in the same periodical [2]. More recent summaries are those by Jacobs and Whitehead [16], which contains 419 references, and Boldyrev [17] which contains 202 references. Both publications discuss the thermal decomposition and combustion of AP, which are important aspects with regard to its use as a rocket propellant. We have attempted to incorporate most of these aforementioned references in the current summary of the available literature and have further expanded the literature search to include more recent publications.

The production of AP, the main ingredient of composite solid rocket propellants, far outpaced that of the other perchlorates. It was not until 1928 that GFS Chemicals began producing magnesium perchlorate for use as a desiccant (“Anhydrone”, “Dehydrite”), which led to perchlorate salts becoming available on the US market. Up until 1940, the total worldwide production of perchlorates had not exceeded 3.6 million pounds. An abrupt change in production was realized with the onset of World War II and the resulting increase in demand for rocket and missile propellants. Annual perchlorate production quickly increased to 36 million pounds because of this demand and remained at a high level thereafter. By 1974, perchlorate production in the US had reached 50 million pounds.

An excellent summary of the history of perchlorate production in the US was written by one of the key contributors to this remarkable development [4]. According to this account, an Air Corps Jet Propulsion Project at the California Institute of Technology contacted the Western Electrochemical Company (WECCO) Inc. in December 1942 to establish a domestic source of perchlorates for use in solid rocket propellants. Up

until this time the production of chlorates was mainly for matches and pyrotechnics. WECCO constructed a perchlorate pilot plant in Los Angeles. Experimental quantities of potassium perchlorate and AP were produced as required by the US Air Corps. In 1943 WECCO designed and built a large-scale plant in Los Angeles to produce potassium perchlorate with a capacity of 100 short tons/month. It expanded its capacity a year later to 200 short tons/month. WECCO designed another potassium perchlorate plant to be constructed in Henderson, NV, with a capacity of 1200 short tons/month, which started operation in 1945 in a converted magnesium electrowinning plant. The KClO_4 was used in jet-assisted take-off (JATO) rockets for heavy airplanes. Four of the principals of the JATO rocket project at Guggenheim Aeronautical Labs at the California Institute of Technology (GALCIT) later went on to found Aerojet. Even today, Aerojet remains one of the key rocket propulsion companies in the US and a consumer of AP.

WECCO began production of AP in a small plant in Henderson, NV, in 1947, and then built a larger plant with a 50 short tons/month capacity that began production of AP in 1953 and became part of American Potash and Chemical Corporation in 1955 and Kerr-McGee in 1967. Other temporary perchlorate producers during WW-II were Cardox in Claremore, OK (KClO_4 , 1941–1945), Vick Chemical in Greensboro, NC (NH_4ClO_4 , 1943–1945), and Electric Reduction Company in Canada. In the post-WW-II era, other AP producers were Hooker & Foote (Columbus, Mississippi) and PennSalt in Portland, OR.

Early in the 1950s, the Solvay Division of Allied Chemical developed a new process for on-site generation of OCIO for the bleaching of paper pulp, starting with sodium chlorate solution. This increased the competing demand for sodium chlorate to a point where the perchlorate production needed to be set up to its own chlorate electrolysis units. In the early 1960s, alternate methods for the production of AP were sought, including the reaction of ammonium sulfate with sodium perchlorate [18].

A new production facility was established by the Pacific Engineering and Production Company (PEPCON) in Henderson, NV, which was operated by WECCO employees. Late in the 1960s with Minuteman, Peacekeeper, Polaris, and Trident in position, it appeared that the AP demand had peaked and was likely to drop. At that moment, NASA (National Aeronautics and Space Administration) decided to design the Space Shuttle with solid propellant boosters instead of liquid propellant boosters. This advanced the AP business for a further 40 years. In 1998 American Pacific Corporation (AMPAC) acquired the AP business of Kerr-McGee Chemical Corporation. As of 2011, the WECCO at Cedar City, UT, became a division of AMPAC. AMPAC still has a PEPCON division but this only deals with water treatment and not in AP production. Since 1998 AMPAC is the only North American producer of AP.

Recent production data for AP as well as for the other perchlorate salts are lacking. In 1994, production of AP in the US was estimated at 22 million pounds or just 36% of capacity. Actual production volumes for AP have been historically dependent on the demand for aerospace and military applications due to its predominant use in rocket

propellants. This use has resulted in defining AP as a strategic chemical. However, current worldwide production figures are not readily available.

Perchlorate ion is recognized as an impurity in the production of electrochemically produced chlorine products, including sodium chlorate. The pulp and paper industry uses most of the sodium chlorate consumed in the US for on-site production of OClO to bleach cellulose fibers. Sodium chlorate has also been used as a non-selective contact herbicide and a defoliant for cotton, sunflowers, Sudan grass, safflower, rice, and chili peppers. Assuming a sodium chlorate consumption rate of approximately 10^9 kg per year and a 0.01% perchlorate content, a source strength of roughly 10^5 kg per year was calculated. However, only a fraction of that would find its way into the environment.

The Census Bureau in the US does not list perchlorates as a separate reportable item on its Schedule B book on imports or exports. Instead, perchlorates are lumped together under the general category of perchlorates, bromates, perbromates, iodates, and periodates. The total amount of imports for this category was 1.867×10^6 , 1.881×10^6 , and 1.281×10^6 kg for 2005, 2006, and 2007, respectively [19]. Exports totaled 1.349×10^6 , 2.067×10^6 , and 1.927×10^6 kg in 2005, 2006, and 2007, respectively (USITC, 2008). Notably, in the wake of the detection of perchlorate contamination in many aquifers and surface waters in the US, the EPA has assembled a database of perchlorate manufacturers and users and is keeping track of perchlorate imports and exports.

In the aftermath of the explosion at AMPAC Henderson and the shutdown of its Kerr McGee facility in Henderson, the authorities have struggled to secure an adequate AP supply for national defense and space program use. It took several steps to restore the industrial base for AP production. The WECCO and Kerr-McGee Chemical Corporation were allowed to add a surcharge to the per-pound price of AP to repay the loan for the rebuilding of the PEPCON plant and for the relocation of and improvements made to the Kerr-McGee plant. The US government guaranteed an annual AP purchase for 7 years to buy 20 million pounds from Western Electrochemical and 30 million pounds from Kerr-McGee. In the event that surcharge payments were not sufficient, US Department of Defense (DoD) and NASA would pay additional AP procurement fees. The surcharge payments to Western Electrochemical were based on amortization of the 92 M\$ cost to build a new AP production facility in Cedar City, UT. Surcharge payments were concluded as of March 1992 after the US government paid 41.7 M\$ surcharges to both producers.

Each launch of the space shuttle consumed about 680 metric tons (1.5 million lb_m) of AP. The AMPAC plant in Cedar City has a capacity in excess of 13600 metric tons (30 million lbs) per year but the production rate as of 2004 was closer to approximately 5000 metric tons (11 million lbs) per year [20].

2.1 Production Methods for Ammonium Perchlorate

The average rocket propellant chemist will rely on a source of AP and would not have to know how it is made. However, stability and performance of AP depends on impurities that are carried over from the manufacturing of this chemical. Therefore, to have full confidence in the adequate quality of the oxidizer and the solid rocket propellants made therefrom, one must know how this chemical is produced. Most of the AP is created by a metathetical reaction of sodium perchlorate (from electrolysis of sodium chlorate) and ammonium chloride:

The process can be carried out continuously by feeding a chlorate-free sodium perchlorate solution to a stirred reactor (A) with anhydrous ammonia and aqueous hydrochloric acid at 363 K (90 °C) [21–23]. As illustrated in Figure 1, the reaction product stream is withdrawn continuously and fed to a crystallizer (B) where the water is removed by lowering the pressure. The AP crystals are withdrawn from the crystallizer as a slurry and the crystals are separated from the liquid in a continuous centrifuge (C). The wet crystals are washed with water and dried. The mother liquor is fed to a second crystallizer (D) where NaCl precipitates and the supernatant liquid from that step is returned to the first reactor.

Figure 1: Flow diagram of continuous AP production process. (Reproduced and modified from [21].)

The hazards of producing AP were well-known in the chemical industry when they first started producing it in quantity for fledgling US missile programs [24]. Nonetheless, the disposal of the brine from this process has become a major environmental problem after years of negligence where the brine was allowed to evaporate in unlined ponds. Waste sodium chloride salt crystallized from the brine was even sold as highway deicing material for several decades until the leaching of perchlorates into aquifers and drinking water sources was detected and caused an environmental uproar. Corrective action has been taken since and strict environmental regulations are now in place for the disposal of waste products from AP production. However, it will take several decades until all perchlorate contamination is flushed from the aquifers and streams.

Perchloric acid and AP of high purity can be produced by electrolysis of chloric acid and subsequent reaction with ammonium hydroxide in a proprietary Olin process. The process involves no alkali metals, chlorides, or transition metals, and thus produces propellant and explosive grade AP of high purity and with no associated instability or pollution problems. The products can be recovered by solution crystallization drying or direct spray drying, respectively.

In the process at AMPAC, sodium chlorate is dissolved in DI water and the solution is filtered to remove insoluble residues. The solution is electrolyzed to convert sodium chlorate to sodium perchlorate, which is crystallized and dried for storage. Ammonium chloride solution is made on-site by reacting anhydrous ammonia and aqueous hydrochloric acid. The ammonium chloride solution is then reacted with sodium perchlorate solution. The less soluble AP precipitates in a two-step crystallizer; it is filtered and dried and some of the brine goes back into the NaClO_3 electrolysis cells.

Only two materials can be used as anodes in the industrial production of perchlorates: platinum and lead(IV) dioxide. Platinum is very costly while lead-dioxide, on the other hand, is very cheap. Unfortunately, due to its brittle nature, it requires a suitable substrate over which it has to be coated to form an anode. An AP production plant in India adopted the less expensive lead dioxide as the anode material [25]. The previously used Graphite Substrate Lead-Dioxide Anodes (GSLA) had several disadvantages such as short service lives and low current efficiency. A new anode system based on Titanium Substrate Lead-Dioxide Anodes (TSLA) was developed to overcome these problems. Due to its superior corrosion resistance, the titanium substrate could be re-used after the useful service life of the lead-dioxide coating. The TSLA system was found to be superior to GSLA with respect to the current efficiency, cell voltage, and reusability of the substrate. The TSLA system was only one-tenth as costly as platinum but produced almost the same current efficiency. The AP production plant in India achieved a production rate of 800 tons/y.

2.1.1 First Crystallization of AP

Freshly prepared AP is rarely crystallized in the same shape in which it is used for making rocket propellants. Preparing it in small particle size at the production facility would be futile because the crystals tend to agglomerate during transport and storage. Also, finely ground AP is in a higher transportation hazard category than coarser particle size AP.

Some alternate methods for first crystallization are discussed here. Some of the particle size comminution technology described here for AP could just as well be used for other oxidizers. This more general information on process design for granular materials and other oxidizers belongs into a later volume on Composite Solid Propellants.

2.1.2 Recrystallization of AP

Recrystallizing is the preferred method for purification of AP. This step is encountered when AP is manufactured the first time and also during an important process while recycling AP that has been washed off from demilitarized rocket motors. Recrystallizing under special conditions may also result in smaller crystal size AP that gives a higher burning rate.

AP is recrystallized by batch crystallization. This is done by cooling a saturated aqueous solution. The cooling rate is consistently maintained by using a cooling-rate controller so that the decrease in temperature is linear. The amount of agitation during the cooldown influences the product size distribution. Supersaturation is inevitable and needs to be carefully reviewed. In one process optimization experiment, the supersaturation was observed by means of a refractometer for three different cooling rates [26, 27]. The results showed quantitatively how the rate of cooling determines the supersaturation levels and consequently how the particle size of the product is affected. Supersaturation is very high during primary nucleation and decreases during crystal growth and secondary nucleation. The extent of secondary nucleation is determined by the particle size distribution of the product.

Spherical or near-spherical shapes of oxidizer particles allow for more uniform packing density and lower viscosity of the poured propellant. Rounded AP particles can be obtained by pouring irregularly shaped AP powder with a specific particle size into a saturated solution of AP in water and stirring it vigorously for 0.2 to four hours at 13500 to 3000 RPM at a constant temperature, thus wearing off the sharp edges [28]. An alternate method starts with a saturated solution of AP in water that is stirred vigorously while it cools down. In the latter case the particle size is determined by the rate of cooling.

AP, which is grown as whisker crystals with whisker diameters from one to five μm , offers improved high burning rates in composite propellants. Further accelerated propellant burning rates would require sub-micron diameter material. The same method can also be applied to production of whiskers which are doped with co-crystallized burning rate catalysts [29].

A saturated aqueous solution of AP oozing through the pores of a porous (fritted) glass tube coated with a polymeric silicon evaporates in warm air. This forms long AP whiskers with length-to-diameter ratios of 10 : 1 to 100 : 1 [30]. The crystals continue to grow as long as the tube is fed the AP solution. The crystals fall off under their own weight or can be scraped off with a spatula and dried. The whiskers can be stored under ambient conditions without loss of optimum ballistic performance. This is better than freshly ground AP crystals which require immediate use after grinding as they tend to agglomerate with time and aging. A similar phenomenon of whisker growing can be observed in wet basements of houses when gypsum crystals grow on the surface of porous masonry while ground moisture permeates the foundations.

Most spray drying methods for AP use just plain water to dissolve the salt. However, if very small particle sizes such as ultra-fine AP (UFAP) are needed, adding a volatile solvent to the solution before spraying it will result in droplet breakup by flash evaporation and smaller oxidizer particle sizes.

Acetone, ethanol (15–85 vol.-% in water), or methanol (70–100 vol.-% in water) were tested as potential solvents [31]. The mean diameter of AP particles decreased with increasing concentration of the organic solvent and increasing inlet temperature of hot air, but this bottomed out at 1.3 to 2.2 μm . The finest AP was produced with 100% methanol and a drying air temperature of $>313\text{ K}$. Mixing AP with flammable solvents is a hazardous operation [32].

In order to prepare a crystal-habit-modified AP, a saturated solution of AP at 333 K was poured into butanol cooled to 273–275 K [33]. In one study, crystallization of AP was carried out with two mixture ratios: One was a mixture of butanol and saturated solution [9 : 1 by volume, named as (B-1)], and the other was a 3 : 2 mixture in volume ratio [named as (B-2)]. AP obtained by crystallization from distilled water was ground for ten minutes in a vibration ball mill and was used as a reference AP for comparison. AP obtained by the above three methods was used as an oxidizer for composite propellants and their processability and burning characteristics were compared. The results were as follows: **(1)** Maximum AP contents of propellants using (B-1), (B-2) and reference AP were 63.5, 76.0, and 86.5 mass-%, respectively. Maximum AP solid loadings of propellants using (B-1) AP and (B-2) AP were considerably lower because (B-1) and (B-2) are dendrite-shaped. **(2)** Subsequently, (B-1) AP was ground for five to 30 minutes in a vibration ball mill. (B-1) AP was ground for five minutes, (B-2) AP was ground for three minutes, and the reference AP had approximately the same particles size and specific surface area. Propellants containing 80 mass-% AP were prepared using these three grades of AP. Following measurement of their burning rates it was found that the propellant using (B-1) AP ground for five minutes had the highest burning rate. Propellants using (B-2) AP ground for two minutes had the next highest burning rate. It was suggested that crystal habit modification can have an effect on increasing the burning rate.

An attempt was made to modify the crystal habit of AP by adding *n*-hexane. The particle characteristics of the crystal-habit-modified AP and the burning rate charac-

teristics of the composite propellant using the crystal-habit-modified AP were investigated [34]. It was noted that: **(1)** The crystal shape of the modified AP is dendritic. **(2)** The intensity of the lattice plane (011) of the modified AP is remarkably high. It was found that the crystal habit of AP can indeed be modified by hexane. **(3)** The thermochemical behavior of the modified AP was almost the same as the typical behavior of AP. **(4)** Both the mean particle diameter of the modified AP and the modification degree of crystal habits were decreased by grinding.

Water-soluble polymers as crystal-growth modifiers are gaining more frequent use in the field of morphogenesis of inorganic crystals. AP particles with a particular morphology were crystallized by a polymer-assisted crystal-habit modification route using poly(vinyl alcohol) [35]. AP crystals with a rectangular prism and a rectangular wedge shape were obtained. The X-ray diffraction (XRD) patterns revealed that the phase of AP obtained was the same as that obtained from saturated solutions.

Crystal-habit-modified AP allows one to produce propellants with increased burning rates [36]. The modified AP crystals often have a dendritic shape. However, dendritic AP is not convenient to mix and cast in an AP/binder slurry because of its high viscosity. A crystal-habit-modified AP with polygonal or spherical shapes was prepared by redissolving and precipitating in ethylene glycol such that the intensity of the lattice plane (210) of the modified AP was remarkably high. The shape was almost hexahedral, and the mean particle diameter was approximately 150 μm . The crystals were characterized via scanning electron microscopy (SEM) and XRD and their sensitivity was determined by the drop weight impact test.

A ceramic membrane solvent/anti-solvent crystallization method was tested for the safe and rapid preparation of superfine AP crystals [37]. Acetone and ethyl acetate were chosen as the solvents and anti-solvents. The ceramic membrane with a regular pore structure allowed one to control the feeding rate, size, and morphology of AP. Several types of micron-size AP particles with different morphology were obtained including particles with polyhedral-, quadratic prism-, or rod-like shapes. Higher volume ratios of anti-solvent to solvent, higher feeding pressures, and higher temperatures resulted in smaller particle sizes.

The effect of crystallization parameters such as cooling patterns, agitator rpm, retention of crystals in the mother liquor, and the presence of surfactant on the morphological, thermal, and physical characteristics of AP crystals was examined in a 5-L capacity laboratory glass crystallizer [38]. It was found that spherical, transparent, and smooth-surface crystals can be obtained by crystallization having a slow cooling pattern and an agitator rotation rate of 600 rpm. Irregular-shaped crystals were obtained with fast cooling patterns and/or lower agitator rpm. Crystals made in the presence of a surfactant and examined by SEM, bulk density, and the transparency of crystals had some porosity.

Recrystallized AP has modified crystal habits and different thermal and morphological properties [39]. The morphology of AP crystals is affected by the presence of ethylene glycol during crystallization [40].

2.1.3 Freeze-Drying of AP Solutions

Freeze-drying of a frozen solution of 8–10% AP in water is described in detail in a patent [41]. An aqueous solution of AP is flash-frozen in a dry ice bath and the ice is sublimed at below freezing in a vacuum chamber at $<50\mu\text{m Hg}$ pressure. Water is the preferred solvent because that makes this process safer than other processes that use flammable solvents. Average particle sizes varying between 1.7 to $2.1\mu\text{m}$ have been obtained this way.

The early objective was to establish freeze-dried UFAP manufacturing methods for the economical production of UFAP with a weight median diameter (WMD) ranging from $1.0\mu\text{m}$ to less than $0.5\mu\text{m}$. Emulsion formulation affects product quality and, therefore, a flow viscometer for emulsions was developed, calibrated, and used to characterize the emulsions. With proper emulsion and rapid freezing in a rotary drum freezer, the achievable size range is between 0.3 to $0.6\mu\text{m}$ weight mean diameter. The ultimate goal of this project is the process design for a 1000000 pounds per year UFAP processing facility. Spray freezing with a centrifugal spray device was evaluated as an alternate method.

The freeze-drying process described in US Pat. No. 3685163 [42] involves forming an emulsion of aqueous AP and an organic liquid immiscible with water and a non-solvent for AP, then freeze-drying the emulsion for recovery of the UFAP product. The emulsion can be flash-frozen by pouring it into liquid nitrogen. The frozen material must then be kept at below 233 K (-40°C) while freeze-drying is in progress and at low pressures. The emulsion to be freeze-dried must retain its stability during the entire freeze-drying process in order to preclude separation and coagulation of solution droplets with accompanying formation of unduly large AP product particles. In most instances an emulsifying agent is required for maintenance of the emulsion stability. However, the emulsifying agent does not separate from the AP particle product. Hence, it constitutes a process impurity material, which comes to be incorporated into the propellant. The ratio of aqueous phase: immiscible phase must be optimized to obtain the smallest possible UFAP particle size (Figure 2). Particle sizes of UFAP produced using this method were in the sub-micron range.

The initial AP concentration in the water is 5 to 15% AP. If less than 5% is used, the process is not economical. If more than 15% is used, the difference in density between the aqueous solution and the oil makes it difficult to obtain a stable emulsion.

UFAP handling, storage, and shipping properties were investigated with respect to product coatings, solid propellant formulation processing, and rocket ballistic parameters [43]. Approximately 40 compounds were evaluated and six materials were identified that protect UFAP from particle growth during storage and handling. It was demonstrated that coated UFAP could be stored for several months under low (30%) R.H. humidity conditions and at temperatures up to 333 K (60°C), but not under high humidity and temperature conditions. Ballistic and processing evaluations revealed wide variations in properties with different types and blends of UFAP and different coating materials. A dramatic effect of humidity on the ballistic properties of propel-

Figure 2: Optimization of water/oil phase ratio. (Reproduced and modified from [42].)

lants made with UFAP was demonstrated by making two identical batches of propellant, one from UFAP stored at 10% R.H. for one week and the other stored at 50% R.H. for one week. Burning rate decreased with increasing storage humidity and the mix was very viscous before it could be poured. Aziridine-coated UFAP prepared from the SWECO Vibro-Energy Mill was more readily processible than samples of freeze-dried or fluid energy milled UFAP. Applying hydrophobic coatings introduces combustible organic compounds into an oxidizer, resulting in an increase in explosive sensitivity of the material. The sensitivity heightened as the content of the coating material was increased.

UFAP particles can be made by spraying an aqueous AP solution containing a surface active agent onto a moving film of a refrigerated organic liquid. This forms fine frozen droplets and, by freeze-drying [44], recovering fine AP particles from the frozen droplets.

Ultra-fine porous AP (PAP) consisting of sub-micron particles can be obtained by flash-freezing the solution in liquid nitrogen and then freeze-drying it [45]. The freeze-dried AP was investigated by SEM and XRD. There was no effect of freezing on the crystallinity of AP.

If a saturated aqueous AP solution is poured into a glass vessel and the pressure in the vessel is lowered to <0.1 mm Hg, the saturated solution will freeze. Most of the

water will be sublimed when the vessel is kept at <0.1 mm Hg for 36 hours at room temperature (293 ± 5 K = 20 ± 5 °C), leaving a residue of fine AP crystals [46]. This product was investigated by SEM, Brunauer–Emmet–Teller (BET) surface area measurement, drop-weight impact sensitivity testers, and XRD. Freeze-dried AP were mostly needle-like shaped crystals (diameter 2–5 μ m and a specific surface area of ~ 2.4 m²/g). When 2 mass-% of a surface-active agent was added to the saturated solution prior to freeze-drying, the shapes and the properties of the product were almost the same as those of freeze-dried AP prepared without the use of surface-active agents. The crystallinity of freeze-dried AP was similar to that of ground AP.

AP/hydroxy-terminated polybutadiene (HTPB) propellants prepared with mixtures of freeze-dried UFAP and ground AP had burning rates that increased with increasing UFAP content [47].

Nano-AP was made using a non-aqueous method by dissolving AP in methanol, followed by adding the dissolved AP to liquid HTPB prepolymer, homogenization, and vacuum distillation of the solvent [48]. The nano-AP thus formed was characterized using a particle size analyzer, transmission electron microscopy (TEM), XRD, and SEM for particle size, purity, and morphology. The data indicated that the particle size of the prepared AP was in the range of 21–52 nm and the thermal decomposition temperature was lower than for coarse AP. Nano-AP composite propellant formulation with 86% solids loading revealed a 14% increase in burning rate in comparison to standard propellant composition, and still had desired mechanical properties.

2.1.4 Precipitation of AP in a Solvent/Non-Solvent System

A process that can potentially operate as a continuous process instead of a batch process is described in a patent [49] where a solution of AP in tetrahydrofuran (THF) is poured into a stirred non-solvent (a high-boiling hydrocarbon). The precipitate is allowed to settle following which the decanted supernatant fluid is fed to a distillation apparatus. The THF is distilled off and more of the precipitate filtered from the hydrocarbon suspension is drained from the pot. The THF vapors are condensed in a cooler above a trickle bed, packed with raw AP, where it saturates itself on the way down and re-enters the process. AP crystals with narrowly controlled particle sizes (1.2, 31, or 61 μ m) were produced by this method.

Another process for making UFAP by freeze-drying emulsion proceeds as follows [50]:

- a. Forming an aqueous solution of AP then mixing this solution with an organic liquid immiscible with water and a non-solvent for AP.
- b. Adding a branched-chain HTPB with a molecular weight not exceeding about 2500 and a diester emulsifier to the resulting mixture, then agitating the resulting mix to form an emulsion of an organic liquid as continuous phase and an aqueous AP solution as dispersed phase.

- c. Flash-freezing the emulsion by pouring it into liquid nitrogen.
- d. Subliming the organic liquid and ice from the frozen emulsion.
- e. Then recovering the residual UFAP particles produced by the process.

The UFAP thus produced had particle sizes of less than $1\mu\text{m}$. The mean diameter of the UFAP depends on the interfacial tension between the organic solvent and the AP solution. Addition of a surfactant will reduce the particle size but foaming may cause problems [51].

The precipitation of AP from methanol solutions of AP by a solvent/non-solvent method using diethyl ether, chloroform, methylene chloride, or isobutanol yields rounded crystals [52]. When ether, chloroform, or methylene chloride were the non-solvent precipitants, the product had a particle size less than $5\mu\text{m}$, but crystals obtained with isobutanol as the precipitant had an orthorhombic shape and the mean crystal size was larger than $10\mu\text{m}$. The precipitation ratio of the four salting-out solvents improved in the sequence isobutanol, methylene chloride, chloroform, diethyl ether. The characteristics of the precipitated AP crystals were investigated by SEM, XRD, differential scanning calorimetry (DSC), and thermogravimetric analysis (TGA) and were found to be very similar.

Rounded and finely divided oxidizer particles can be obtained by applying high-frequency acoustic vibrations during the cooling of the solution or evaporation of part of the solvent [53]. Thus, a stirred saturated AP solution at 368 K (95°C) was placed in a water bath at 288 K (15°C) and subjected to 20 kHz ultrasound while cooling. After 24 hours the acetone- and diethyl ether-washed and dried precipitate consisted of uniform and round shaped $70\text{--}180\mu\text{m}$ particles. A similar solution treated for five hours at 90 kHz yielded rounded $10\text{--}20\mu\text{m}$ particles. The method can also be applied to hydrazinium nitroform or and nitronium perchlorate.

Another method for production of UFAP uses saturated aqueous solutions and chills them in an emulsion with a heavy, non-miscible solvent like methylene chloride (dichloromethane) and ultrasonic agitation [54]. By using a non-solvent phase, growth of the precipitated crystals is prevented and a large proportion of fine particles become suspended in the non-solvent liquid layer below. In one example, chilled methylene chloride was poured into a saturated solution of AP with ultrasonic agitation. Lecithin may be added as an emulsifying agent. After ceasing the agitation, sub-micron-size particles of AP settled into the lower layer and were separated and dried from the non-solvent. The particle size ranged from about 0.6 to $4.5\mu\text{m}$ with about half the particles in the sub-micron size. Other non-miscible fluids suitable for this process are chloroform, perchloroethylene, carbon tetrachloride, trichloroethylene, 1,1,2-trichloro-1,2,2-trifluoroethane, 1,1,2,2-tetrachloro-1,2-difluoroethane, or 1,1-dichloro-1,1,2,2-tetrafluoroethane.

2.1.5 Grinding of AP

General information on grinding of solid propellant ingredients will be provided in a later volume in this series. Grinding of AP is a hazardous operation as AP can ignite if it overheats during grinding, particularly so if the grinding is pushed to the limit by producing UFAP, which is detonable under certain conditions.

Grinding of AP crystals may leave fractures and residual stresses in the particles. It is typically at these disturbed locations that thermal decomposition of AP starts around the nuclei after the ground material is processed into a propellant and if it becomes exposed to high temperatures. Notably, AP with small particle sizes can be made by mechanical crushing through dry milling in a spiral jet mill (classifier mill) [55].

Aerojet developed a facility which was designed to simultaneously produce five different particle size ranges in bulk or in smaller batches [56]. Raw material arriving in 2265-kg (5000-lb) bins is transported by dry air to one of four grinders from a central location. Grinding is remotely controlled for safety reasons and optimum reproducibility of the particle size of the completed product.

An intermediate grade of fine AP, which is coarser and easier to manufacture than UFAP, is a grade called [special fine AP] (SFAP) which was developed by the Thiokol Chemical Corporation. [57]. Special fine AP is AP in the particle size range 4 to 7 μm . Average particle sizes are often measured as [weight mean diameter] (WMD). WMD is the theoretical diameter of the 50% point by weight of a sample. Three commercially available grinders were evaluated for their ability to produce AP in the desired SFAP particle size range but only one was rated to be able to grind AP this small. The Micro-Pulverizer is a hammer mill but was not able to produce anything smaller than 14 μm WMD. The Micro-Bud hammer mill could not produce anything smaller than 9 μm WMD. The Jet-O-Mizer specification promised particle sizes in the desired range but its throughput was much slower than the other two mills. The Jet-O-Mizer is a vertical elongated torus fluid energy mill. Particle comminution occurs by particle-to-particle impact and the energy is provided by tangential air inlets.

AP can be continuously ground in a jet mill with helium or nitrogen gas [58]. The highest grinding efficiency and sub-micron-sized fractions were achieved when heated helium was used. It was proposed to continuously mix the ground oxidizer with the other granular propellant ingredients dispersed in an inert gas in a specially designed mixing tube.

Grinding equipment is prone to wear down with continued use, and although the grinding tools are much harder than the AP they are grinding, wear on the surfaces will change the clearance between the moving and stationary surfaces and cause the particle size to change during the life of the machine. Continuous particle sizes and particle size distribution measurements are required to assure a reproducible product. Statistical process control can help to identify deviations from normal product properties and trigger corrective action before the ground AP is processed into propellants [59]. The target size is a nominal 16 to 20 μm grind of AP. The reproducibility of a statistically

significant number of grinds made over a two-year period on a production line was analyzed statistically to assure reproducibility. The time period during this process included two mill rebuilds, which introduced an additional variable.

Microfine AP (with particle sizes as small as $5\mu\text{m}$) can be produced by grinding under high-frequency low-amplitude vibration in refrigerant R 113. This method also enhances safety. Solid loadings $>87\%$ in a composite aluminized propellant were attained by using a trimodal particle size distribution of AP (coarse, fine, and microfine) [60]. Even at 90% solids the propellant had good processability with a density of 1.84 g/cm^3 .

AP has been pulverized by an impact mill (air classifier mill) to study the influence of different operating parameters, viz., effect of mill speed, classifier speed, feed rate, and damper opening (suction rate) on the particle size [61]. Further, based on the different grinding parameters, an empirical equation was then developed to predict the size of particles. The experimental results indicated that the values were very close to the predicted ones. In addition, particle size distribution has also been studied by applying different model equations; it has been found that the Rosin-Rammler model is the most suitable model for this operation.

The effects of particle size on propellant slurry viscosity and ballistic parameters are well documented, however, the effect of oxidizer particle shape is not well understood. Therefore, different methods for size and shape characterization were examined and the effects of size and shape of AP on composite propellant properties were studied [62]. The data indicated that as the size of AP decreased, the propellant slurry viscosity and the burn rate increased. An examination of the effect of the size of ground AP particles on their shape revealed that as the size of ground AP decreased, the shape factor decreased and particles became more irregular in shape.

A superfine powder of AP with a particle size of $2\mu\text{m}$ was obtained by crushing in a jet mill under optimized technological conditions [63]. The electrostatic problem during AP crushing is a safety hazard. However, a way to eliminate electrostatic charge build-up was found to ensure the safety of the crushing process.

Sub-micron AP was prepared in a vertical stirring grinding machine by controlling the grinding time, rotating speed, and the feed rate of the materials [64]. The dispersing medium used was *sec*-Butyl alcohol. The final products were obtained by using a vacuum freeze-drying method. Particle size distribution, grain sizes, and crystal structures of these AP particles were characterized by laser particle size analyzer, field emission SEM, and XRD. This showed that the AP had an average particle size of 460 nm. The friction sensitivity, impact sensitivity, and TGA of sub-micron AP was compared with that of coarse AP; it was found that the friction and impact sensitivities had increased (worsened) by 20% and 18.7%, respectively. In the differential thermal analysis (DTA) (with a heating rate of 10°C/minute), the high-temperature decomposition (HTD) peak temperature of sub-micron AP had decreased by 60°C , and the activation energy of decomposition was reduced by 27.3 kJ/mol .

In one study, AP was first ground by a jet mill, and then superfine spherical AP particles were prepared by a planetary ball mill [65]. Their morphologies, particle size, and shape and IR spectra were characterized by SEM, Micron laser particle size analyzer, and FTIR. Bulk density and thermal mechanical properties of superfine spherical AP and non-spherical AP with the same size were characterized. The impact sensitivity and friction sensitivity, hygroscopicity, and caking of superfine spherical AP and non-spherical AP with the same size were studied. The results revealed that superfine spherical AP prepared by the milling method had good sphericity, smooth surface, and fewer defects. The thermal decomposition peak moved to a lower temperature in the DSC. The impact sensitivity and friction sensitivity of superfine spherical AP were lower than those of the non-spherical AP and hygroscopicity and caking were effectively improved.

The relationship between particle size and the impact or friction sensitivity of UFAP has been analyzed [66]. Not all grades of AP produce the same desirable small particle size results upon grinding. The grindability of AP from three different sources revealed some differences [67]. The thermal stability of AP fine particles comminuted by grinding or by recrystallization may be quite different [68].

2.1.6 Agglomeration of UFAP

Once UFAP is produced, problems arise with regards to how to keep the crystals from agglomerating and growing back together ("caking"). Thermodynamically, the agglomeration of small particles is favored because it results in a decrease of entropy. The tendency of AP to cake together even while perfectly dry during long-term storage at ambient temperatures was attributed to ion mobility. This allows ions to spontaneously move around and rearrange themselves. Coatings that can retard the agglomeration of UFAP during storage, between production and formulating it into a propellant, have been evaluated.

The particle growth rate of uncoated fluid energy milled AP (1.7 μm) was determined by exposing samples at two temperatures and three different relative humidities [43]. Particle growth persisted in all six test conditions. It was concluded that simple storage conditions will not prevent particle growth of uncoated UFAP. Most of the growth occurred during the first 24 hours of storage. Coated samples could be stored at 10% R. H. for ten weeks without noticeable particle growth.

Various coatings have been applied to UFAP during the precipitation and crystallization to prevent the small particles from agglomerating during storage and to act as bonding agents to the organic polymer when processed into propellants [69]. Sub-micron particle size AP particles are made by mixing a solution of AP in a volatile liquid with a less volatile liquid which is miscible with the first liquid and is a non-solvent for AP. The resulting mixture is then heated to vaporize the volatile liquid and form a suspension of fine AP particles in the second less volatile liquid. A particle coating agent soluble in the second liquid was used to limit particle growth of the finished

product. The ultra-fine particles were coated with the coating agent and could be recovered from the suspension by vaporization of the second liquid to form a powder or by partial vaporization of the second liquid to form a concentrated slurry or paste in which the AP was the disperse phase.

Surface modification of UFAP (0.5–1 μm diam.) was evaluated to prevent agglomeration during production and storage [70]. Neither single-component anti-static agents nor single-component moisture-proofing materials and friction modifiers prevented coagulation but some surface-active agents can inhibit coagulation. Fresh unmodified UFAP had combustion performance that is similar to modified AP. However, after a few days of storage, the performance of the unmodified samples deteriorated whereas the surface-modified materials did not.

Various surfactants which impose negative or positive charges on the particle surface were evaluated to see if they promote or retard agglomeration of UFAP in colloidal suspensions [71]. The effectiveness of such additives depends on the type and quantity of the media and on the surface-charge characteristics of the additives, dispersity, stability, and coagulation tendency of the particles. When the particles were suspended in trichloromethane, the stability of the particles was better than in other liquids. When the particles were suspended in mixtures of organic liquids and water, some additives had an advantage with maintaining the stability and dispersity of the particles. Such agents included surfactants of the anionic, non-ionic, and cationic types. Mixtures of additives, such as mixtures of two or more surface-agents, and an anti-foaming agent were better for the dispersity and stability of the particles. Usually the total quantities of the additives are ~0.1–0.5 mass-% (based on the weight of the AP).

One of the methods to avoid the agglomeration of superfine AP powder is to coat AP raw material with nitrocellulose (NC) and then crush the coated AP in a jet mill [72]. AP coated by this method had reduced hygroscopicity. After being stored for 30 days in air, it had no aggregation and its particle size remained at about 2.5 μm . Coating AP with NC can prevent the superfine powder of AP from agglomerating and makes it possible for the superfine AP to be used for the propellants with high burning rates, even after extended storage in dry air.

The anti-caking mechanisms due to the use of surfactants in AP crystalline products were examined [73]. The influence of surfactants and impurities in anti-caking matrix-liquor from different manufacturers on anti-caking properties of AP crystals were investigated by storage and sieve analysis tests. The results revealed that surfactants from different manufacturers can have different anti-caking effectiveness. Cl^- and Ca^{2+} contamination in anti-caking matrix-liquor has a remarkable influence on anti-caking properties of AP crystals. Surface modification of the AP not only minimizes the troublesome caking but also reduces the hazards due to build-up of electrostatic charges during processing. Surfactants and inert powders were used as anti-caking, anti-static additives [74].

2.1.7 Porous AP

While it is usually the objective to prepare dense oxidizers without porosity, a special form of PAP has been developed and tested for the sake of higher burning rates. PAP can be prepared using methods very similar to those used for UFAP. A fluidized-bed pilot-scale process was developed to produce PAP in small quantities [75]. The burning rate of propellant prepared with PAP was higher than that of propellant with regular AP. To facilitate mixing with a binder and to further improve the burning rate, PAP can be coated with a solution of the prepolymer adduct of divinylbenzene and ethyleneimine [76].

Another method of preparing AP with ultra-high surface area for propellants with ultra-high burning rates is by thermally shocking AP crystals (mean diam. 180 μm) by heating to ~423 K (~150 °C) followed by rapid cooling then multiple extractions with EtOH and/or BuOH for formation of indentations and/or cavities on the surface, crevasses, and tunnels within the crystals [77]. Thermal shocking produces microcracks which are etched by the solvents to produce indentations and porosity with highly pitted surfaces in which the pits have a rather large length-to-width ratio oriented with their long sides parallel to one another, thus having the appearance of terraced pyramids. Subsequent coating with a hexane solution of divinylbenzene forms a thin coating to prevent agglomeration. This product can be used as a direct replacement for porous NH_4ClO_4 produced by thermal decomposition at 422–478 K (300–400 °F) but has improved burning rate, tensile strength, strain at maximum stress and break, modulus of elongation, and extinguishing properties.

PAP can be produced by fluidized bed technology on a laboratory scale. The burning rate of a composite propellant could be greatly increased by partially substituting PAP for the granular AP while the mechanical properties of the propellant would remain unchanged [78]. The burning rate of a fast-burning composite modified double base propellant with 34–38% PAP was about three times that of an AP propellant with no special catalysts.

Notably, the PAP discussed here must not be confused with the porous residue that is left behind after the first phase of a two-step decomposition has been completed (see Section 4.3.3).

2.1.8 Coatings for AP

AP and other oxidizers for solid propellants may be coated to make them less hygroscopic and to prevent agglomeration. It can also be used to achieve better bonding with an organic polymer in a composite propellant formulation. Several anti-caking agents have been listed in the previous chapter which discussed UFAP.

Tricalcium phosphate (TCP) is used as an anti-caking agent in AP. AP and TCP assay analyses cannot be carried out by estimating the insoluble calcium salt in water because a reaction takes place between TCP and AP in aqueous solutions. This is evident from the release of ammonia. It was concluded that TCP in the presence of AP is

not stable and should not be used in composite rocket propellants which have critical composition [79].

Kinetic studies revealed that, in binders involving epoxy resins and carboxyl groups in polybutadiene-acrylic acid-acrylonitrile terpolymers, the rate of the polymerization reaction is reduced and the epoxy groups in Epon[®] H-825 are consumed faster than carboxyl groups in the presence of AP. Over 200 different coatings were evaluated to prevent or retard the oxidizer-epoxide interaction. The coatings can be adsorbed from solutions of AP and deposited on a fluidized bed of the oxidizer, or merely added to the propellant formulation [80]. Coatings evaluated include polyethyleneimines, linear polyalkylenepolyamines, alkylamines, amides and polyamides, quaternary ammonium compounds, fatty acids and polymerized fatty acids, and a variety of polymers.

Controlled modification of surface characteristics of AP is possible by ions common to AP production, surface coating with metal oxides and salts, and surface coating with various non-ionic, anionic, and cationic surfactants. Tests revealed that surface modification had measurable and significant effects on the viscosity, wettability, and thermal properties of AP in propellant blends. Optimization and control of surface properties can lead to improvements in formulation, storage stability, and ballistic properties of AP-based solid propellants.

Impact sensitivities of AP coated with eight different polymers including bonding agents and binders were much higher (more sensitive) than those of uncoated AP [81]. Coating by encapsulation caused sensitization while simple mixing did not lead to the same results.

Bonding between AP and HTPB, constituting a non-reinforcing filler system, has been studied in the presence of a new bonding agent, a zwitter ion molecule, which is the 2,4-dinitrophenylhydrazone derivative of 1,1'-bisacetylferrocene (DNPHD AF) [82]. Extensive conjugation and a permanent ionic character make the DNPHD AF bond strongly with the ionic oxidizer AP. Through its terminal —OH group, HTPB bonds with the NO₂ groups of DNPHD AF.

AP is often coated with bonding agents to improve the bond between the inorganic oxidizer and the organic binder. It is important to select only bonding agents that are compatible with AP that do not react prematurely or during the curing of the propellant [83]. Fourier transform infrared (FTIR) spectrometric analysis of coated AP revealed that the interfacial bonding force is by hydrogen bonds for aziridine type compounds and ionic bonds for alkylene polyamine derivatives, respectively.

Tepanol[®] (a tetraethylenepentamine acrylonitrile glycidol adduct with polar hydroxyl and nitrile groups attached) has been evaluated as an AP coating. Saturation of the oxidizer surface with ionic Tepanol was intended as a means of inhibiting AP low-temperature decomposition (LTD) reactions. If a coating by Tepanol bonding agent saturated all available ionic sites on AP particles, some lattice energetics would cover external AP surface ions where decomposition usually starts. Expected improvements were: (1) A reduction of one atmosphere burn rate and (2) inhibition of the AP LTD pro-

cess. If one atmosphere burn rate was slowed, higher inputs for electrostatic discharge (ESD), drop weight impact, and friction tests might be needed to obtain propellant ignition.

The alkalinity of polyamine bonding agents such as Tepanol will cause evolution of ammonia when reacted with AP in chloroform. For propellants containing 0.15 mass-% Tepanol, the total weight of ammonia generated per unit weight of propellant was equivalent to 120 ppm [84]. Successful application of these bonding agents is, therefore, dependent on how well the ammonia byproduct can be dissipated from the mix before the isocyanate curing agent is introduced because otherwise the propellant might blister. Ammonia generation by the bifunctional aziridine-based bonding agent system HX-752 was found to be 25 times less severe (on a week-by-week basis) than Tepanol. HX-752 is, therefore, better-suited to applications where removal of ammonia is impractical such as continuous process mixing. Diethylenetriamine (DETA), which is used to reduce the propellant viscosity to processable levels (<25 kPs), generated up to five times as much ammonia (on a week-by-week basis) as Tepanol in chloroform/AP slurries but required less than two hours to react completely.

To avoid ammonia formation other bonding agents based on vinyl ethers have been developed [85]. There is no increase in ammonia liberated above baseline propellant values and no increase in end of mix viscosities with these coatings.

The properties of coated AP were analyzed by a solubility experiment and DSC [86]. The combustion properties of coated AP propellant were tested and the mechanism of reduction of the AP burning rate and pressure index by coating was explained. It was found that coated AP reduced the burning rate and pressure index of AP/HTPB composite solid propellants.

Fluorocarbon polymer coatings can be used to enhance thermal stability and electrostatic protection of composite propellant compositions. A technique has been developed to coat AP with a copolymer of hexafluoropropylene and vinylidene fluoride (HFP-VF) using a solvent-counter solvent precipitation method [87]. The coated AP is then used to prepare AP/HTPB/Al propellants and compared to similar propellant made with uncoated AP. Viscosity build up and visco-elastic behavior as well as mechanical, ballistic, thermal, and sensitivity properties were measured while keeping solids loading at 86%. The data on viscosity build up indicated that as the percentage of coated AP increased, end of mix viscosity and viscosity build up increased accordingly. The burn rate of the composition also increased with a higher percentage of HFP-VF coated AP. The thermal stability of the composition increased as the percentage of HFP-VF coated AP was increased. The data on sensitivity indicated that impact sensitivity decreased on increasing the percentage of HFP-VF coated AP while no change was observed in friction sensitivity value.

Metal oxides like iron(III) oxide serve as oxidizers in thermite-type igniter formulations. The igniter formulations can be improved by replacing the metal oxide particles with AP that have been coated with a metal oxide coating. Coated AP was incorporated

into a nanothermite composite formulation [88]. The perchlorates were encapsulated through a series of thermal decomposition, melting, phase segregation, and recrystallization processes. This occurred within levitated aerosol droplets. Several samples, including $\text{Fe}_2\text{O}_3/\text{KClO}_4$, CuO/KClO_4 , and $\text{Fe}_2\text{O}_3/\text{NH}_4\text{ClO}_4$ composite oxidizer particles were created. The results revealed that these composite systems significantly outperformed the single metal oxide system in both pressurization rate and peak pressure. The ignition temperatures for these mixtures were significantly lower than those of the metal oxides alone.

Thermal stability of AP particles can be improved through micro-encapsulation techniques. A solvent/non-solvent method was used to micro-encapsulate AP particles with polymer films such as Viton A and NC [89]. The thermal stability of coated AP was examined using DSC, TGA, and SEM. Further to this, the heat of decomposition and coating morphology of pure and coated samples was documented. Viton significantly and unfavorably attenuated the heat of AP decomposition. Therefore, NC was chosen as a more appropriate coating material for AP. The thermal analysis of NC-coated samples, prepared at optimized coating conditions, revealed that the first stage decomposition temperature increased by about 12°C with respect to uncoated samples and reached 578 K (305°C). Micro-encapsulation of AP particles with fibrous NC enhanced its heat of decomposition ($\sim 120\text{ J/g}$) with no obvious adverse effects on kinetic parameters and thermal decomposition temperature.

The influence of mineral wax and dioctyl phthalate (DOP) coatings on the impact sensitivity of AP was studied by measuring the impact sensitivity of the coated AP powder and examining the surface with SEM [90]. The results revealed that the effects on impact sensitivity of AP were different for mineral wax and DOP. Due to gas release that occurs in the low temperature stage, the impact sensitivity of coated AP was increased by adding dioctyl phthalate and was decreased by coating AP with mineral wax. The study indicated that the endothermic material was better for reducing the AP impact sensitivity.

To reduce the hygroscopicity of AP, the surface of AP crystals was coated with polystyrene (PS) and fluorosilane (FAS: $\text{C}_{14}\text{F}_{12}\text{H}_{20}\text{SiO}_3$) films [91]. AP/PS/FAS composite particles and AP/PS/FAS composite film were prepared via composite of AP and PS and the processing of FAS. The hygroscopicities of coated AP samples were studied via moisture absorption rates and a water contact angle test and their micromorphology structures were investigated by scanning electron microscope (SEM)-energy dispersive X-ray analysis (EDAX). The moisture absorption rate of AP/PS/FAS film was the lowest of all samples tested and it almost no longer absorbed any moisture. It was found that FAS molecules exist on the surface of AP/PS/FAS films where they form a hydrophobic surface.

The hygroscopicity of AP can be decreased by modifying the surface of AP. In one experiment, AP was coated by graphene oxide (GO), AP/GO mixtures were modified by fluorosilane (FAS: $\text{C}_{14}\text{F}_{12}\text{H}_{20}\text{SiO}_3$), and a binary coating of AP mixtures was applied [92]. Testing of the moisture absorption rate in an atmosphere of 85% rela-

tive humidity (R.H.) at 293 K (20 °C) revealed that the moisture absorption rate was reduced. The moisture absorption rate of AP and AP/GO composites decreased further after they were modified by fluorosilane. The minimum moisture absorption rate was attained by a binary coating method where the concentration of GO was 0.40% and the concentration of fluorosilane was 1%. Thermal analysis revealed that the high peak temperature of the exothermic decomposition of AP/GO/FAS mixtures decreased by 33 °C when the concentration of GO was 0.40% and the concentration of fluorosilane was 1%.

In order to reduce the mechanical sensitivity of AP superfine powder, octadecylamine was used as the coating agent and coated superfine AP particles were prepared by jet milling [93]. The coating effect, thermal decomposition characteristics, and sensitivity characteristics of coated superfine AP particles were studied by particle size analysis, SEM, DSC, and sensitivity testing. Experimental results revealed that the particle size of coated superfine AP particles was 5.8 μm , with a coating layer present on the surface. Compared with the pure AP superfine particles, the impact sensitivity of coated superfine AP particles with 1 mass-% coating was reduced by 31% and friction sensitivity was decreased by 12%. When the mass fraction of coating agent was increased to 3%, the impact sensitivity of coated superfine AP particles was reduced by 34.5% and friction sensitivity was decreased by 22%. However, the coating agent had some negative impacts on the thermal stability of AP. As such, it is recommended that its concentration should be kept below 1 mass-%.

Fumed silica coatings act as desiccant and prevent agglomeration of UFAP [94]. Various other coating materials have been evaluated for preserving the properties of UFAP during storage [95].

Coatings with several inert materials, including some functional carbon materials, paraffin wax, and the well-known insensitive energetic material 1,3,5-triamino-2,4,6-trinitrobenzene (TATB) were evaluated to reduce the undesirable high sensitivity and hygroscopicity of UFAP via polymer modified coating [96]. Structure, sensitivity, thermal and hygroscopicity of the UFAP-based composites were studied by SEM, sensitivity tests, DSC, wetting contact angle, and hygroscopicity analysis. The results revealed that both the impact and friction sensitivity of UFAP can be remarkably reduced with only a small amount of 2 mass-% of desensitization agents, while thermal stability was improved and hygroscopicity was reduced to a large extent at the same time.

Coatings of nanothermites, such as $n\text{CuO}/n\text{Al}$ ($n\text{Al}$), $n\text{MoO}_3/n\text{Al}$, $n\text{Fe}_2\text{O}_3/n\text{Al}$, $n\text{NiO}/n\text{Al}$, and $n\text{MgO}/n\text{Al}$ encapsulated into AP had higher activity in decreasing the decomposition temperature of AP, thus increasing the heat release and ignition and combustion properties than the corresponding physically-mixed mixtures [97]. The lowest decomposition temperature of AP was shown by $n\text{Al}/n\text{CuO}/\text{AP}$, which demonstrated the highest heat release and best ignition and combustion properties among all the composites tested.

3 Physical Properties of Ammonium Perchlorate

The molecular mass of AP is 117.489 g/mol. This number is needed to convert thermochemical properties from a mass basis to a molar basis and vice-versa.

3.1 Melting Point of Ammonium Perchlorate

The melting point of AP at atmospheric pressure is difficult to measure because the material begins to decompose and sublime before it melts. In addition to this, melting is preceded by a solid-solid phase transition at 513 K (240 °C), which further complicates the issue. The melting point of pure AP is unknown since it decomposes or even explodes beforehand.

3.1.1 Melting Point Diagrams of AP Mixtures

AP can be mixed with many other oxidizers to obtain desirable properties, for instance with reduced hydrogen chloride output in the exhaust gas. The main oxidizer candidate for such mixtures is AN. In fact, many AP/AN composite propellants have been formulated and tested. Similar mixtures have been discussed in the AN chapter in *Encyclopedia of Oxidizers*.

3.1.1.1 Melting Points of AP Mixtures With Other Ammonium Salts

The most attractive mixture of ammonium oxidizers is the mixture of AN and AP, possibly combining the advantages of both oxidizers in one propellant ingredient. The mixture would have better performance than AN and emit less environmentally objectionable hydrogen chloride in the exhaust than AP. Before AP/AN mixtures can be used, the physical properties must be known, in particular their tendency to undergo phase transitions with sudden changes in density and crystal shape.

Unfortunately, the complete diagram could not be obtained because the liquidus temperature at 12% AP was high enough to cause rapid decomposition of AN [98]. The freezing point and melting point of AN/AP mixtures in the range from 0–12 mol-% AP are shown in Figure 3. The mixtures tend to undercool before they crystallize. This is why the two lines are not on top of each other.

There appear to be two closely located, incompletely resolved eutectics melting near 427 K (154 °C) with compositions in the range from 6.8 to 8.1 mol-% AP, at which point it was difficult to obtain accurate measurements. XRD data indicated the existence of a peritectic at about 8.2 mol-% AP. The freezing point curve (solid line) shows a minimum whereas the melting curve (dashed line) drops to a low value (close to that of the eutectics) and remains there, regardless of the AP content. The dashed line is erratic and unusable. Both AN and AP undergo phase transitions, which affect their mechanical and thermal stability properties. It was of interest to see how the phase

Figure 3: Freezing/melting point diagram of the AN/AP system. (Graph created by Schmidt, 2020, based on data from [98].)

transitions would be affected by adding the other oxidizer. In AN, the transition at 399.6 K (126.5 °C) corresponds to the transition from cubic to rhombohedral. This transition persisted across the entire part of the phase diagram studied. The transition temperature dropped rather sharply (about 2 °C) over the first 0.5 mol-% of AP added. After this, it remained constant within the accuracy of the measurements. This slight drop in the transition temperature corresponded to the region of solid solution formation. On the AN-rich side of the diagram the cooling curves remained at a constant temperature during the transition. As more AP was added, the transition occurred over a temperature range rather than at a particular temperature. This temperature range increased with the AP content.

Another phase diagram revealed that the melting point in the AP/AN system does not drop significantly until the AN concentration reaches 80% AN. Then the melting point drops sharply toward a eutectic containing 90% AN and melting at 419 K (146 °C) [99].

AP is the most popular oxidizer, however, it is not the cleanest. Its environmental impact can be reduced by adding nitrates. Solid propellants containing both AN or phase stabilized ammonium nitrate (PSAN) and AP are called “dual oxidizer” composite propellants. The AN and AP can be dry-mixed as individual powders or the two salts can be co-crystallized from water and then ground to the desired particle size. AN and AP can be co-crystallized by freeze-drying [100]. AN adhered to the less soluble AP particles during the drying process to form combined AP/AN particles. The AN content of the combined AP/AN samples dominated particle properties, including shape, hygroscopicity, thermal decomposition behavior, and ignition sensitivity.

Several propellants were formulated with the co-crystallized oxidizer and compared to conventional AP-based propellants [101] (see [102]).

3.1.1.2 Melting Points of AP Mixtures With Other Perchlorate Salts

Lithium perchlorate is an oxidizer with a very high oxygen content. Mixtures of lithium perchlorate with AP could potentially improve the performance of rocket propellants using mixed oxidizers. Liquidus temperatures for samples containing more than 40 mol-% AP could not be obtained because of rapid decomposition of this salt as the temperature was raised. Decomposition of samples containing less than 40 mol-% AP was negligible. The phase diagram of the binary system $\text{LiClO}_4/\text{NH}_4\text{ClO}_4$ shows that the system has a simple eutectic at 69.5 mol-% LiClO_4 at 455 K = 182 °C (Figure 4) [103].

Figure 4: Phase diagram of the $\text{LiClO}_4/\text{NH}_4\text{ClO}_4$ system. (Reprinted and modified from [103], with permission from © 1959 American Chemical Society; permission conveyed through RightsLink.)

AP with 1 mass-% of lithium perchlorate added can survive heating at 543 K (270 °C) for up to 24 hours without any noticeable indication of thermal decomposition. Eutectic formation in the $\text{NH}_4\text{ClO}_4/\text{LiClO}_4$ system has been credited with a stabilizing effect that extends the range of thermal stability of AP [104]. The crystallographic transition characteristic of AP persisted throughout the composition range studied (55-0 mol % LiClO_4).

A eutectic containing 30.5 mol % (32.64 mass-%) AP and 69.5 mol % LiClO_4 has a higher solubility in polymerizable monomers. It is more easily processed into homogeneous dissolved polymer solid propellants than either AP or LiClO_4 [105].

Addition of sodium perchlorate to AP would lower the available oxygen content somewhat but would also reduce the amount of chloride emitted in the objectionable form of hydrogen chloride. Instead, some of the chloride escapes as sodium chloride, which is benign and settles out of the atmosphere and dissolves in the ocean where there is already plenty of it.

3.1.1.3 Melting Points of AP Mixtures With Other Salts

Another oxidizer suitable as an additive to AP is sodium nitrate. Although sodium nitrate does not have a high useable oxygen content, the presence of sodium in the exhaust scavenges some of the chloride and emits it as inert sodium chloride rather than as toxic and corrosive and ozone-depleting hydrogen chloride. Essentially, similar results at a fraction of the cost could be achieved using mixtures of sodium perchlorate with ammonium nitrate. Furthermore, sodium perchlorate is less expensive than AP. The related phase diagram of ammonium nitrate with sodium perchlorate is shown in *Encyclopedia of Oxidizers* (“Nitrate Oxidizers” chapter).

3.1.1.4 Melting Point Diagrams of AP Solutions

The freezing point depression as the result of dissolving AP in water is 0.709° at $0.2135 \text{ mol AP}/1000 \text{ g H}_2\text{O}$, 1.189° at $0.3616 \text{ mol AP}/1000 \text{ g H}_2\text{O}$, 1.755° at $0.535 \text{ mol AP}/1000 \text{ g H}_2\text{O}$, and 2.656° at $0.8069 \text{ mol AP}/1000 \text{ g H}_2\text{O}$. The eutectic point in the system $\text{NH}_4\text{ClO}_4/\text{H}_2\text{O}$ is $270.4 \text{ K} = -2.72^\circ\text{C}$ and contains 9.84 mass-% AP.

3.1.2 Phase Changes of AP

3.1.2.1 Phase Changes of AP at Atmospheric Pressure

At ambient pressure and temperature AP crystallizes in the orthorhombic crystal system. Space group $Pnma$ and the ammonium ions are allowed essentially free rotation. Variable temperature studies indicate that, at least up to 78 K, ammonium ions undergo increasingly large amplitude rotational oscillations about definite equilibrium positions. Under ambient conditions of temperature and pressure, AP exists in an orthorhombic crystal structure ($Pnma$) in which the NH_4 ions freely rotate. Despite numerous reports of anomalies in a variety of physical properties of AP in the temperature range 10–298 K, a definitive study using neutron diffraction, inelastic neutron scattering, and Raman spectroscopy has shown that there is no evidence for any phase transition in this temperature range [106]. On heating to above 511–513 K, AP undergoes an orthorhombic to cubic phase transition in which almost unrestricted rotational orientation of the perchlorate ions is observed [107]. The rotation of the cations, however, begins below room temperature. On heating to above 511–513 K, a reversible phase transition to a cubic structure takes place in which there is almost unrestricted rotational reorientation of the perchlorate ions. AP exists in three solid phases: a low-temperature phase, an orthorhombic crystal structure phase, which is stable from 83 to 513 K, and a high-temperature phase, which is cubic and stable from 513 K to the melting point 723 K.

All alkali metal perchlorates except lithium perchlorate undergo phase changes from (bipyramidal) orthorhombic to cubic when heated and so does AP [108]. The dimorphic transition temperature has been explained as the point where the ClO_4^- anion begins to rotate freely in the crystal structure. AP undergoes a reversible phase change at 513 K (240 °C). This temperature is close to its melting point and point of incipient thermal decomposition. Below 513 K, AP exists in the form of orthorhombic crystals. Above 513 K, AP exists in the form of cubic crystals. The phase transition orthorhombic $\rightarrow$ cubic is endothermic but it is accompanied by incipient thermal decomposition. The rate at which AP converts to the cubic crystal phase from the orthorhombic crystal phase is relatively slow compared to chemical reactions. It is difficult to measure the enthalpy of the phase transition in a DSC or DTA because incipient decomposition of AP releases additional heat. It was possible to suppress the decomposition by heating AP in a stream of ammonia (see Section 4.6.6.3) [109]. The enthalpy of transition measured in this way is +9.6 kJ/mol (2.3 ± 0.2 kcal/mol) (an average of ten determinations). The calculated density of orthorhombic AP is 1.95 g/cm³ whereas the high-temperature form has a density of only 1.76 g/cm³ for a volume difference of 9.7%. Even if a rocket motor is not accidentally igniting if heated above 513 K (240 °C) (a very hazardous condition that should be avoided), the volume expansion of AP which usually makes up 80% of the propellant may rupture the motor casing (in the case of an end burner) or cause the coaxial perforation or cavity to choke for simple mechanical reasons. Choking the perforations may cause excessive pressure build up because the combustion products have no way to escape.

The orthorhombic to cubic transition occurs via slippage of planes moving parallel to each other to create rectangular crystal faces. When cubic AP is cooled to below 513 K (240 °C) the crystal forms many grains, with each grain having an orthorhombic structure. However, the macroscopic appearance of the whole crystal remains cubic. This state has been referred to as “relic cubic”.

Thermal decomposition of AP proceeds differently depending on if one starts out with an orthorhombic or cubic modification. The orthorhombic form of AP decomposes faster than the cubic form. Also, the effect of additives on the dissociation of AP is different depending on which modification exists at the moment when the additive is stepping into action [110]. A third rarely seen modification exists below 83 K. It was suggested that the transition at 83 K is associated with thawing the cation free rotation, whereas the 513 K transition corresponds to the onset of perchlorate ion rotation.

A comparative study of polymorphic transformations in ammonium and the alkali metal perchlorates using DTA developed correlations between the observed trends in the transformation temperatures and available crystallographic and thermodynamic data [111]. Considerable hysteresis was observed in the transformations in ammonium, potassium, rubidium, and cesium perchlorates. Doping of AP with ammonium phosphate caused an upward shift in the transformation temperature and an increase in the thermal hysteresis. Prior mechanical and thermal treatment resulted in a broadening of the hysteresis loops in the case of ammonium and potassium perchlorates.

The enthalpy of phase transformation was measured as $20.3 \pm 0.6 \text{ cal/g} = 2.39 \pm 0.07 \text{ kcal/mol} = 9.99 \text{ kJ/mol}$ [112]. DSC operations were carried out at heating rates of 2, 4, 8, 16, 32, and 64 K/min. The activation energy for the phase change endotherm was measured by scanning methods and was derived from three different equations. The activation energy derived from the equation $\log S/\Delta H$ versus $1/T$ was $667 \text{ kJ/mol} = 159.5 \text{ kcal/mol}$.

When studying polymorphous transitions in AP crystals, it was discovered that there are two mechanisms of the transformation of the rhombic modification into the cubic one [113]. At low temperatures the transition follows an atom-by-atom mechanism. At temperatures above 516 K (243 °C) the transition is of the martensite type. In both cases the polymorphous transition proceeds through the formation and growth of nuclei of the new phase; the growth of martensite nuclei occurs not continuously but incremental. The interface boundary can be coherent during the transition from the rhombic modification into the cubic one.

An ESR study of free radicals in X-irradiated AP single crystals was aimed at resolving the controversy that had arisen over the possible occurrence of low-temperature phase transitions in AP, which at room temperature has an orthorhombic structure (space group *Prma*) [114]. ESR spectra revealed no changes attributable to any phase transitions. It was concluded that AP does not undergo any phase transitions below room temperature.

3.1.2.2 Phase Changes of AP at Very High Pressures

The structural behavior of AP at high pressures is poorly understood. For instance, several studies reported in the literature appear to contradict each other. The pressures where the phase transitions take place are much higher than typical rocket operating pressures but all phase changes need to be understood to make sure they do not take place unexpectedly as with ammonium nitrate.

A strong pressure dependence on the orthorhombic to cubic transition temperature was observed when AP was compressed to 0.4 GPa. The orthorhombic to cubic transition that occurs at 511 K at ambient pressures has been followed as a function of pressure up to 0.4 GPa and a very strong pressure dependence (216 K/GPa) of the transition was observed. However, subsequent optical studies revealed that it was only weakly pressure-dependent [115]. The high-pressure phase diagrams of NH_4ClO_4 and NH_4BF_4 were studied using DTA and volumetric techniques [116]. The usual orthorhombic $\rightarrow$ cubic transition was followed by up to 4 kbar and 573 K. AP exploded violently at 602–623 K and 2–3.6 kbar, although this would only happen above 713 K in atmospheric pressure. The explosion may be due to the large volume change upon phase transition. The high-temperature portions of these diagrams were intermediate between those of the corresponding potassium and rubidium salts. However, at low temperatures, the onset of hydrogen bonding caused the appearance of phases which are unique to the ammonium compounds.

AP demonstrated previously unreported phase transitions when pressurized and heated in a diamond anvil cell at high temperatures (up to 693 K) and high pressures (up to 26 GPa) [115, 117]. These studies also reported the pressure dependence of the solid-liquid transition and claimed that there was no evidence for a high-pressure phase transition up to 26 GPa. Liquid droplets were observed above the well-known orthorhombic to cubic phase transition at 513 K and were interpreted as signs of incipient melting. The melting point decreased with increasing pressure. A phase diagram was constructed showing all the different phases. Preliminary high-pressure DSC data revealed a weak pressure dependence of the orthorhombic to cubic phase transition. Unexpectedly, Foltz and Maienschein [115, 117] found that the temperature of AP phase change was reduced by increasing the pressure. Since increased pressure should resist a volume increase and with small thermodynamic energy forcing the phase change, one would anticipate that increased pressure would instead cause a rise in phase change temperature. Foltz and Maienschein had difficulty taking measurements at low pressures while observing AP phase change behavior. Their lowest pressure at phase change temperatures was about 10 kbar (~ 1.0 GPa, ~ 145000 psi).

Crystal structures have been measured by XRD at pressures up to 5.0 GPa under conditions of shock compression. A change in the powder pattern was reported at 4.70 GPa, and the authors suggested that, on the basis of its complexity, the pattern was characteristic of a monoclinic or triclinic unit cell [118].

Using a combination of XRD and neutron diffraction techniques, augmented by vibrational spectroscopy, structural information of fully deuterated d-AP was measured at pressures up to ~ 8 GPa [119]. Under hydrostatic conditions d-AP undergoes a first order phase transition at 3.98 GPa, which is in agreement with the results of previous studies. The structure of the new orthorhombic phase (*Pnma*), which features a more closely packed structure with more extensive hydrogen bonding, was resolved and an equation of state for this new phase at pressures up to 8.1 GPa was obtained. High-pressure techniques were used to investigate polymorphism in energetic materials and new high-pressure phases of AP were structurally characterized using single-crystal X-ray and powder neutron diffraction [120].

Infrared studies of AP revealed a change in the ν_1 mode of the perchlorate group between 1.0 and 2.4 GPa [121, 122]. This was assigned to the orthorhombic to cubic transition. Single-crystal shock-wave studies revealed no obvious phase transformations but suggested that if any phase transition did occur that it would be accompanied with a negligible change in volume or with very slow kinetics [123, 124].

Calculations of the polymorphic phase stability, structural transition, and lattice dynamics of AP under high pressure revealed that AP attains a global minimum energy structure in *Pnma* symmetry over *Pna2₁* [125]. However, the difference is very small at ~ 1 meV per formula unit. The calculated phonon dispersion curves indicated that AP is dynamically stable in both *Pnma* and *Pna2₁* crystal symmetries at ambient pressures, which unambiguously shows the existence of polymorphism in AP. The *Pnma* phase of AP was found to be mechanically unstable above 4 GPa. AP undergoes a first-order

structural phase transition above 4 GPa. The high-pressure phase crystallizes in orthorhombic crystal symmetry ($P2_12_12_1$) at 6.9 GPa, which is consistent with the recent experimental results.

3.2 Density of Ammonium Perchlorate

3.2.1 Density of Solid AP

The densities of the two crystal modifications of AP are quite different. Particle swelling and shrinkage would cause severe delamination problems similar to those of AN if the phase transition point was at a lower temperature. The density of the orthorhombic phase is 1.957 g/cm^3 and the density of the cubic phase is 1.756 g/cm^3 . After AP transitions from orthorhombic to cubic phase at 513 K (240 °C), crystal volume increases by 10.8%. Older sources give the density of the orthorhombic phase at 298 K (25 °C) as 1.9518 g/cm^3 and the density of the cubic phase above 513 K (240 °C) as 1.732 g/cm^3 .

3.2.2 Density of AP Solutions

The density of AP solutions in water is tabulated in Table 1.

Table 1: Density of AP solutions.

Temperature, °C	Ammonium perchlorate concentration, mass-%						
	2	4	6	8	10	12	14
	Density, g/cm^3						
15	1.0088	1.0186	1.0286	1.0387	1.0490	1.0594	1.0700
25	1.0065	1.0160	1.0257	1.0355	1.0455	1.0557	1.0660

Data source: [126].

Once one has an accurate density chart, the concentration of AP solutions can be determined with a thermometer and a hydrometer [127]. The deviations of this crude method are of the order of 4 g/L. The density of saturated AP solutions containing 20% AP at 298 K is 1.0982 g/cm^3 .

3.3 Vapor Pressure and Sublimation of Ammonium Perchlorate

AP exerts a noticeable vapor pressure when heated. The vapor pressure of AP must be taken into consideration when conducting volumetric studies of the thermal decomposition of AP. The rate of sublimation increases faster with temperature than the rate

of decomposition in vacuums. The vapor pressure can be measured either in static or in dynamic systems. The vapor pressure of AP is caused by partial dissociation of AP into ammonia and perchloric acid. No ion clusters or undissociated AP was found in the vapor phase above heated AP. Sublimation papers are now provided in chronological order.

The dissociation pressure of AP was measured using a dynamic transference method [128, 129]. In a number of runs the following parameters were varied:

1. flow rate of helium gas
2. reaction temperature
3. initial mass of AP
4. initial particle size
5. partial pressure of NH_3 added to carrier gas

The vapor pressure can be expressed using the following equation:

$$\log p = -6283.7/T + 10.56$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin. The heat of dissociation is 58 ± 2 kcal/mol in the temperature range of 520–620 K.

The vaporization and sublimation products of AP and other volatile perchlorates as studied by a cold matrix isolation technique and identification of products by IR absorption spectra are ammonia and perchloric acid [130]. Other IR bands found in the products were assigned to NH_3 , HCl , and H_2O . Comparing the vaporization temperatures of AP, hydrazinium perchlorate, hydroxylammonium perchlorate, and methylammonium perchlorate (MEAP), the relative vaporization temperatures could be correlated with the pK values of the bases in aqueous solution.

The kinetics of AP sublimation were investigated over a wide range of temperatures and vapor pressures up to 1 atm [131]. A model for AP sublimation takes both surface diffusion and diffusion through the gas phase into consideration. An equation describing the kinetics of sublimation was in strong agreement with the experimental data. The evaporation coefficient β is strongly pressure-dependent, indicating the importance of surface diffusion in the evaporation process. The AP sublimation process commences by the transfer of a proton from an NH_4^+ ion to a ClO_4^- ion at a disturbed surface kink site. The NH_3 and HClO_4 molecules thus formed remain adsorbed at these positions for a finite time. Unless they can diffuse away to become adsorbed on separated sites away from the surface step the proton-transfer process will reverse itself and the ions will recombine. At low pressures, the evaporation process is then completed by the desorption of NH_3 and HClO_4 molecules into the gas phase.

It is difficult to study the sublimation of AP without running into unwanted decomposition problems. There are several studies where sublimation and decomposition of AP have been measured simultaneously. Methods for rapidly heating a solid body of AP include hot wires, hot foils, laser, and hot air convective heating. AP specimens (pellets that are 0.156 inches in diameter and 0.5 to 1 inch in length) were ex-

posed to various levels of convective surface heating from a gas burner at one atmosphere ambient pressure [132, 133]. Previously, linear pyrolysis rates were obtained by pressing specimens against heated plates (solid and porous) and heated wire meshes. Surface regression rates were measured and, simultaneously, surface temperatures were determined by measuring the IR emission near $3.1\text{ }\mu\text{m}$. The results appear to corroborate the previously suggested value of 83.68 kJ/mol (20 kcal/mol) for the apparent activation energy for AP pyrolysis (see [134].)

In the early 1970s the activation energies reported for AP sublimation varied considerably, from 84 to 126 kJ/mol (20 to 30 kcal/mol) depending on the method used. A mass-spectrometric thermal analysis method was used to study the kinetics of the sublimation of AP and attempts were made to consolidate data from different sources [135]. The AP sample was held in a titanium cup and placed in a heated tube close to the Knudsen cell inlet and ionization electrodes of the mass spectrometer.

DTA demonstrated that the addition of inorganic salts to AP, or preheating AP, delays the sublimation process, rendering AP more suitable for solid rocket propellant use [136]. Sublimation was enhanced by precompression of the pellets and by decreasing the particle size from 500 to $200\text{ }\mu\text{m}$. Reducing the particle size further to $100\text{ }\mu\text{m}$ led to a reduction in rates of sublimation. It is assumed that imperfections and residual strain in the crystals caused these effects.

The sublimation of AP was investigated by using simultaneous DTA and TGA [137]. Critical evaluation of the isothermal kinetics of data obtained by a thermobarogravimetric technique indicated that the kinetics are consistent with an expression for a contracting cylinder rather than a contracting sphere model. The activation energy for sublimation obtained experimentally is in strong agreement with that derived from the Schultz-Dekker theory ($75.3 \pm 8.4\text{ kJ/mol} = 18 \pm 2\text{ kcal/mol}$). The sublimation process in AP was compared to that in ammonium halides. It is shown that a previously reported value of 30 kcal/mol for the activation energy was obtained under conditions where decomposition instead of sublimation dominated.

The fact that the activation energy of thermal decomposition of AP turned out to be smaller than the heat of sublimation (88 and 125 kJ/mol , respectively) had been the subject of discussion for some time. It was proposed that a quasi-equilibrium is established on the surface of AP between the crystals and dissociation products, while the limiting stage is desorption of dissociation products (ammonia and perchloric acid). The heat of dissociation of AP into ammonia and perchloric acid has been estimated to be $242\text{--}251\text{ kJ/mol}$ [138].

Time-of-flight (TOF) mass spectrometer measurements of the flux of molecules from the surface of ammonium salts vaporizing into vacuum revealed that, in the case of AP, the vapor subliming from a single crystal surface was comprised of ammonia and perchloric acid [139]. When the source was compressed powder instead of a single crystal, the vapor included a mixture of lower molecular weight species, which may be due to subsurface decomposition. See [140].

The kinetics and mechanisms for the sublimation/decomposition of AP can be represented by first-principles calculations using a generalized gradient approximation with the plane-wave density functional theory (DFT) [141]. The model assumes supercells containing 4, 8, and 16 NH_4ClO_4 units. The predicted enthalpy changes for the reaction of solid NH_4ClO_4 going to gaseous NH_3 and HClO_4 is 188 ± 6 kJ/mol 45.0 ± 1.5 kcal/mol. The calculated desorption activation energies for NH_3 , HClO_4 , and $\text{H}_3\text{N}\cdots\text{HOCLO}_3$ molecular complexes (individually and from the relaxed surface) are 189, 182, and 117.6 kJ/mol (45.3, 43.5, and 28.1 kcal/mol), respectively. The rate constant for the dominant sublimation process desorbing $\text{H}_3\text{N}\cdots\text{HOCLO}_3$ as a pair can be presented by

$$k_{\text{subl}} = A \exp\left(\frac{-E}{RT}\right) = 6.53 \times 10^{12} \exp(-28.8/RT),$$

where k_{subl} is the sublimation constant in s^{-1} (which is in reasonable agreement with available experimental data), E is the activation energy in kcal/mol, and T is the temperature in kelvin. As one would expect, the decomposition of $\text{H}_3\text{N}\cdots\text{HOCLO}_3(\text{G})$ to $\text{NH}_3(\text{G})$ and $\text{HOCLO}_3(\text{G})$ is considerably faster; about 1×10^7 times faster than that for the sublimation process in the same temperature range. The rate constant for the gas-phase dissociation step can be expressed by

$$k_{\text{diss}} = A \exp\left(\frac{-E}{RT}\right) = 1.20 \times 10^{15} \exp(-14.6/RT)$$

where k_{diss} is the dissociation constant in s^{-1} , E is the activation energy in kcal/mol, and T is the temperature in kelvin. This study further confirmed that the activation energy for the sublimation of an ammonium salt is significantly lower than the enthalpic change and that the molecular complex of acid and base sublimates concurrently as a pair.

3.4 Solubility of Ammonium Perchlorate

AP is soluble in polar solvents and is insoluble in non-polar solvents such as diethyl ether or hexane.

3.4.1 Solubility of AP in Water

The solubility of AP in water is summarized in Tables 2 and 3.

The solubility of AP in water can also be expressed as a polynomial function

$$W = 10.696 + 0.3617t + 0.000263t^2$$

where W is the AP concentration in mass-% and t is the temperature in $^{\circ}\text{C}$ (see [142] also).

3.4.2 Solubility of AP in Anhydrous Ammonia

If dry AP is exposed to ammonia gas at atmospheric pressure it becomes deliquescent. AP forms various amines which may contain AP in association with 4 or 6 mols of ammonia. The phase diagram of AP in ammonia is shown in Figure 5. The tetrammine and hexammine adducts are weakly expressed peritectics (points A and B) on the right side of the curve. The eutectic point (point C) of the $\text{NH}_4\text{ClO}_4/\text{NH}_4\text{ClO}_4 \cdot 6\text{NH}_3$ system is at 176 K (-97°C) and contains 49 mass-% AP. The other eutectic points between $\text{NH}_4\text{ClO}_4 \cdot 6\text{NH}_3$ and $\text{NH}_4\text{ClO}_4 \cdot 4\text{NH}_3$ and between $\text{NH}_4\text{ClO}_4 \cdot 4\text{NH}_3$ and NH_4ClO_4 are less pronounced. A solution that is saturated with AP at 283 K contains 72.4% AP and has a vapor pressure just below atmospheric pressure. These solutions are similar to DIVERS solutions containing AN or ammonium thiocyanate.

Figure 5: Phase diagram of the AP/ammonia system. (Reproduced and modified from [126].)

The solubilities of ammonium chloride, potassium chloride, sodium chloride, AP, potassium perchlorate, and sodium perchlorate at 240, 273, 298, and 323 K (−33, 0, 25, and 50 °C) in liquid ammonia have been determined as well as the solubilities of the salt pairs and the ternary mixtures necessary to prepare the quaternary phase diagrams for the two chemical processes

and

These equilibrium diagrams demonstrate the possibility of carrying out the above processes in liquid ammonia [143].

3.4.3 Solubility of AP in Organic Solvents

The solubilities of AP and potassium perchlorate in organic solvents are summarized in Table 4.

The solubilities of AP and other inorganic perchlorates are tabulated in a reference work on solubility [144, 145]. The solubility of AP in methanol as a function of temperature is given in Figure 6 [52]. The solubility of AP in methanol can be expressed by the following equation:

$$C^* = 2.4412 - 1.6665 \times 10^{-2}T + 2.9145 \times 10^{-5}T^2$$

Table 4: Solubility of AP and potassium perchlorate in organic solvents.

Solvent	Solubility, g AP/100 mL saturated solution, at 298 K	Solubility, g potassium perchlorate/100 g solvent, saturated solution, at 298 K
Methanol	6.862	0.1051
Ethanol	1.907	0.012
1-Propanol	0.386	0.010
1-Butanol	0.017	0.0045
iso-Butanol	0.1272	0.005
Acetone	2.26	0.155
Ethyl acetate	0.032	0.0015
Diethyl ether	insoluble	insoluble

Data source: [3].

where C^* is the solubility in g AP/100 g solution and T is the temperature in kelvin. The solid line in Figure 6 was calculated using this equation. This solvent is of practical interest for producing AP with smaller particle sizes than would be possible by recrystallizing them using water. Older sources give the density of a saturated solution of AP in MeOH at 298 K as 0.8218 g/cm³ and it contains 6.41 mass-% AP. It is less solu-

Figure 6: Solubility of AP in methanol. (Reproduced and modified from [52].)

ble in EtOH where a saturated solution at 298 K contains only 1.872 mass-% AP and its density is 0.79505 g/cm³.

AP is insoluble in diethyl ether, methylene chloride, or chloroform but it has a limited solubility in isobutanol (0.1268 g AP/100 g solution).

Most of the solubility work with inorganic oxidizers is done with polar solvents. In the case of AP, however, additional concern has arisen about its solubility in less polar solvents like the hydroxy-terminated polyglycols or polybutadienes it is dispersed in during the processing of composite propellants and prior to the addition of the isocyanate crosslinking agents. The solubility of AP in polyglycols is very small but will affect the oxidizer particle size and thus the burning rate of the final product [146]. AP is sufficiently soluble in polyethylene oxide (polyethylene glycol) to make the polymer electrically conductive.

The solubility of AP in various candidate solvents is of key importance in the selection of solvents for demilitarization of AP-based solid propellants and eventual recycling of the material. The preferred solvent so far has been water but other solvents are evaluated as well.

3.5 Thermal Conductivity and Thermal Diffusivity of Ammonium Perchlorate

Thermal diffusivity measurements on compacted AP powder, pressed pellets of AP, and NaCl (for comparison) from room temperature to 513 K (240 °C) were corrected to extrapolate to solid and non-porous crystal data. The thermal diffusivity of compressed AP powders was measured as a function of porosity, particle size, and temperature. In this temperature range, the thermal diffusivity α of AP can be described by the linear equation

$$\alpha = 2.50 \times 10^{-3} - 4.55 \times 10^{-6} t$$

where α is the thermal diffusivity in cm²/s and t is the temperature in °C [147, 148]. Point data for 323 K are $5.02 \times 10^{-5} \text{ W m}^{-1} \text{ K}^{-1}$ with a heat capacity of $1.134 \text{ J g}^{-1} \text{ K}^{-1}$ ($0.271 \text{ cal g}^{-1} \text{ °C}^{-1}$).

Thermal diffusivities and specific heats of AP, 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), and 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX) were measured from room temperature all the way up to the decomposition temperature region by use of a laser flash method [149, 150]. Radiation heat losses were a significant problem and required the application of a new correction technique. Thermal conductivities were calculated from the thermal diffusivity, specific heat, and density of each material. The diffusivity of AP single crystals was measured along three different directions relative to the crystal lattice. The thermal conductivity (see Figure 7) and thermal diffusivity (see Figure 8) of single crystal AP was found to be independent of orientation. However, it drops markedly at the point of phase transition.

Figure 7: Thermal conductivity of AP single crystals in various directions in relation to crystal planes. (Reprinted and modified from [149], with permission from © 1985 Springer Nature; permission conveyed through Copyright Clearance Center.)

Figure 8: Thermal diffusivity of AP single crystals in various directions in relation to crystal planes. (Reprinted and modified from [149], with permission from © 1985 Springer Nature; permission conveyed through Copyright Clearance Center.)

The conductivities of pressed AP powder pellets were much lower than those of single crystals at $0.0030 \text{ W cm}^{-1} \text{ K}^{-1}$ (compared to $0.0042 \text{ W cm}^{-1} \text{ K}^{-1}$ for single crystals). The thermal diffusivities of AP mixed with a HTPB binder and of HTPB alone were also measured.

Because the thermal conductivity and thermal diffusivity of AP was already well described in existing literature, AP was used as the reference standard for calibrating an apparatus used for the determination of heat capacity, thermal conductivity, and thermal diffusivity of a range of other oxidizers, binders, and rocket propellants [151]. The thermal diffusivity α of AP between the range of 293 to 487 K (20 to 214 °C) can be described by the linear equation

$$\alpha = 2.58 \times 10^{-3} - 4.54 \times 10^{-6} t$$

where α is the thermal diffusivity in cm^2/s and t is the temperature in °C. Likewise, the thermal conductivity λ of AP between the range of 20 to 214 °C can be described by the linear equation

$$\lambda = 1.38 \times 10^{-3} - 9.2 \times 10^{-7} t$$

where λ is the thermal conductivity in $\text{cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1}$ and t is the temperature in °C. Similar data is contained in the same publication for a wide range of oxidizers, binders, and solid propellants.

3.6 Electrical Conductivity of Ammonium Perchlorate

AP has an anomalously high value of electrical conductivity. It is two to three orders of magnitude higher than that of alkaline metal perchlorates, which are similar to AP in their crystal structure and other properties. The activation energy of conductivity is well below that of alkaline perchlorates. The effect of oxygen on the electrical conductivity of AP is quite specific, whereas in the case of alkaline perchlorates, no such oxygen dependency has been observed. Some ammonium salts (e.g., ammonium dihydrogenphosphate) are proton conductors.

There are several methods to arrange information on electrical conductivity in a systematic manner. The following sections could be separated by the method of conductivity measurement used, direct current (DC) measurements (with solid state electrolysis at the electrodes), or alternating current (AC) measurements including impedance measurements at high frequencies. Instead, the material is only arranged in chronological order.

One interesting feature of an ionic solid is the possibility of correlating the creation and destruction of charge carriers by measurement of the DC conductance during its thermal decomposition. A study of the effects of temperature and gaseous environment on the electrical conductivity of AP pellets revealed that, at temperatures between 298 and 398 K (25 °C and 125 °C), argon and oxygen depressed the electrical

conductivity of AP approximately by one or two orders of magnitude, respectively. The activation energies determined from the temperature dependence of the conductivity were 106.1, 111.9, and 135.4 kJ/mol (25.36, 26.75, and 32.37 kcal/mol) for vacuum, oxygen, and argon, respectively. At higher temperatures, the measured activation energy was 32 kcal/mol. The conductivity was increased by the presence of ammonia, showing a first order dependence on the partial pressure of ammonia in the nitrogen carrier gas. The activation energy in the presence of ammonia was 83.7 kJ/mol (20 kcal/mol).

The very first measurements of the electrical conductivity of AP under oxygen, argon, and vacuum produced surprising differences between the three atmospheres which are difficult to explain [152] (see Figure 9).

Legend:	Pressure (mm Hg)	Atmosphere
—	0.01	Air
- - - -	1.0	Oxygen
- · - · -	1.0	Argon

These measurements were made on pressed AP 12-mm (0.5 inches) diameter grains that had been annealed overnight under vacuum at 383 K (110 °C). Obviously, these data would differ from single crystal data.

Electrical conductivity measurements using an applied DC potential were made on an AP single crystal [153]. An interpretation of the conductivity plot has been tentatively based on the assignment of a Frenkel defect structure to the crystal in the orthorhombic form and a Schottky disorder in the cubic form. The energy of migration of a defect has been calculated to be 0.5 eV and the energies for the formation of an ion defect pair are somewhere around 0.6 and 3.0 eV. A plot of electrical conductivity versus reciprocal absolute temperature contains several linear regions. Changes of the

slopes occur at 365, 444, 528, and 583 K (92, 171, 255, and 310 °C). The break at 528 K is also observed in DTA and is attributed to a phase change.

The electrical conductivity of solid AP was measured over a temperature range from 500 to 600 K [154, 155]. From the variation of the ionic conductivity in an applied electric DC field as a function of temperature, the enthalpy of formation of lattice defects was found to be 100 kJ/mol (24 kcal/mol) and the energy barrier for lattice-defect migration was 83.7 kJ/mol (20 kcal/mol). The relatively high electrical conductivity of AP compared with alkali halides and the marked influence of gaseous ammonia on conductivity are interpreted in terms of a mechanism of charge transfer by proton jump. Most of the electrical conductivity measurements were carried out at temperatures above the polymorphic phase transition temperature (513 K). As shown in Figure 10, the conductivity varied from 10^{-10} to 10^{-7} ohm $^{-1}$ cm $^{-1}$ in temperatures ranges

Figure 10: Electrical conductivity of AP as a function of temperature. (Reproduced and modified from [155], in AD-639222.)

between 500 to 600 K. In several experiments, ammonia was added to the carrier gas nitrogen to inhibit sublimation and to explore the influence of ammonia on conductivity. The results indicated that conductivity increased by up to one order of magnitude in the presence of ammonia and depended on the partial pressure of ammonia in the carrier gas (solid line and triangular symbols in Figure 10).

Conductivity data from Wise [155] did not show any discontinuity in going from the orthorhombic to the cubic crystal structure (contrary to observations by other investigators). During the short periods of time required for the measurements, the amount of thermal decomposition and sublimation of AP was found to be small at temperatures less than 575 K, as evaluated from changes in total mass of material.

AP undergoes a phase transformation in the temperature range 513 to 543 K (240 to 270 °C) at atmospheric pressure. The crystal change is from the orthorhombic to the cubic form. Electrical conductivity measurements using an applied d.c. potential, were made on a single crystal of AP. Maycock, Verneker, and Gorzynski [153] studied the electrical conductivity of AP in temperature ranges of 333 to 553 K (60 to 280 °C). An interpretation of the conductivity plot was tentatively based on the assignment of a Frenkel defect structure to the crystal in the orthorhombic form and a Schottky disorder in the cubic form but they did not recognize it as proton conductivity. Their plot of conductivity $\log \sigma$ as a function of reciprocal absolute temperature revealed four distinctly different slopes with breakpoints B, C, D, and E (with the one at 528 K (255 °C) being attributed to the change in crystal structure) (Figure 11).

In the case of AP, the proposed mechanism of protonic charge transport involves movement of a proton from an ammonium ion in the lattice structure to an ammonia molecule located at a lattice vacancy or at an interstitial position [156]. The neutral ammonia molecule thus formed at a lattice site may become the recipient of a proton from an adjacent cation in the lattice as a result, and so on. By this proton transfer charge transport is greatly facilitated compared to that seen with ammonium ion migration via Schottky or Frenkel defects. The measurements carried out with AP single crystals were in satisfactory agreement with those obtained from the pressed pellets of AP. The electrical currents measured for a given applied voltage were not frequency dependent.

Electrical resistance of AP pellets at high pressure with temperature variation revealed no discontinuities [157]. This suggests that no phase transformations occurred. The samples were in the form of disks prepared by compaction of the recrystallized polycrystalline material in a scrupulously cleaned mold at a pressure of 1.238 GPa (180000 psi) at 298 K (25 °C). Hydrostatic pressure on the disk samples was generated with a cubic anvil apparatus. Tantalum foil was the best material for electrical contacts in resistance measurements. This material was found to be inert to AP under the high temperatures and pressures used in this study. Platinum and molybdenum were unsuitable for making resistance measurements. Under the aforementioned conditions, these metals were attacked by AP and produced unreplicable resistance curves.

Figure 11: Electrical conductivity of AP as a function of reciprocal absolute temperature. (Reprinted and modified from [153], with permission from © 1967 Elsevier; permission conveyed through RightsLink.)

The plot of electrical resistance against reciprocal temperature at 1, 2, and 3 GPa in Figure 12 shows none of the discontinuities usually associated with phase changes. It is possible that the application of high pressure prevents transformation since there is a 9.7% increase in volume associated with the transition.

The electrical conductivity of AP changed considerably after irradiation by γ -radiation from a ^{60}Co source, 4.5 MeV protons or X-rays (applied doses of radiation were 6.5×10^{-18} to 9.8×10^{-20} eV/g) [158]. The minimum dose that causes a post-radiation change in the conductivity was determined, as was the conductivity versus the dose over a wide range of doses. Charge carriers in NH_4ClO_4 were negative. The post-radiation conductivity was measured at a continuous heating rate of approximately $2^\circ\text{C}/\text{min}$ at 293–443 K (20–170 $^\circ\text{C}$).

The electrical AC conductivity of pressed pellets and single crystal AP was measured over a wide temperature range and the effect of water and ammonia on conduc-

Figure 12: Electrical resistance of AP as function of temperature. (Reproduced and modified from [157], in NASA-TN-D-6013.)

tivity was examined [159]. The results support the theory of a proton transfer mechanism for the electrical conductance over the entire temperature range studied (298 to 443 K). Adsorbed H₂O or NH₃ act as proton traps. Transfer of a proton from an NH₄⁺ ion to H₂O or NH₃ leaves behind a proton hole, which then gets filled from a neighboring NH₄⁺ ion, and so forth. This process requires only a very small activation energy.

The AC electrical conductivity, both of compressed AP pellets and of AP single crystals, was measured at 1591 Hz from room temperature up to incipient decomposition temperatures [160]. The observed effects of annealing and the partial decomposition that follows require considerable caution to be taken when it comes to accepting various defect models for the conductivity that had been previously proposed in the literature.

The electrical conductivity of single crystals of pure AP and of AP doped with Ba²⁺ ions was measured at a frequency of 1591 Hz between room temperature and 533 K (260 °C) [161]. The crystals displayed a marked increase in conductivity at the temperature of the orthorhombic → cubic phase transition. It was suggested that this sudden increase in conductivity is more likely due to secondary effects (specifically, dislocation generation) than to the actual change in crystal structure. The general similarity between the results for pure and doped crystals tends to support a proton transfer mechanism for AC conductivity that does not involve vacancies. However, vacancies may be important in DC conductance mechanisms.

The hypothesis concerning proton conductivity was verified and confirmed experimentally [162] based on measured changes in the conductivity of AP caused by doping with Ba^{2+} and SO_4^{2-} , the effect of water vapor, ammonia, and temperature cycling. The steps of proton conductivity in AP proposed by Jacobs are (i) proton detachment from the ammonium ion, (ii) its transition to a trap, and (iii) transference of thus formed proton vacancy along the cation lattice.

DC electrical conductivity measurements were reported for sulfate-ion-doped and barium-ion-doped AP [163]. The fact that barium-ion-doped AP displayed no marked differences in electrical behavior from that of the pure salt was used as strong justification for the theory (which later was proved to be erroneous) that the conduction process in AP is controlled by interstitial ammonium ions. Measurements of surface conduction revealed no evidence for proton conduction at or near the surface where such a process would be expected to dominate via sublimation. The dominant point defect structure deduced from electrical measurements, i.e., interstitial NH_4^+ ions, would seem to favor electron transfer from ClO_4^- to NH_4^+ ions as the first step in the thermal decomposition of the solid. This is because this mechanism requires the existence of interstitial NH_4^+ ions (notably, however, this mechanism is not accepted by the scientific community).

Owen, Thomas, and Williams have made arguments in favor of the ion mechanism of conductivity. DC and AC electrical conductivity measurements were made on AP in compressed disc and single crystal form [164]. The near-identity of the electrical conductivity of AP with that of certain alkali perchlorates was cited as argument against conduction by protons. The non-ohmic behavior of AP single crystals revealed that the [classical] theory of ionic conduction based on the migration and creation of point defects is not adequate to fully describe the observed conduction process. The possibility of various electronic mechanisms, including Schottky emission of electrons from the metallic electrodes with associated carrier injection into the crystal, was also discussed. As none of these mechanisms were entirely satisfactory, the electrical conductivity of AP remained a subject of vigorous discussion for several more years to come in the scientific community.

Owen, Thomas, and Williams [165] argued that the ion mechanism of conductivity in AP can be proven by similarity between the activation energies of conductivity in AP and rubidium perchlorate, with the latter compound exhibiting undoubtedly an ion mechanism of conductivity [165]. The DC conductivity and its variation with temperature of single AP crystals and the crystallographically related RbClO_4 was supposed to prove that detached protons and transient NH_3 species are not involved in the bulk migration of charged carriers in NH_4ClO_4 , contrary to what takes place in NH_4Cl . Simple equality of the data on conductivity activation energies for the two solid salts is evidently insufficient to prove the mechanism of transfer processes. Moreover, the ion mechanism did not explain such features of transfer processes as a strong dependence of conductivity on the composition of gas phases above AP (especially on ammonia enrichment and changes in conductivity during thermal decomposition, etc.). As such,

the ion model of conductivity eventually had to be abandoned. This made space for a mechanism based on proton transfer.

On the basis of previous work on the determination of transport numbers, the following mechanism has been proposed for the formation and migration of conducting protons in the AP lattice [166]:

1. Transfer of the proton from cation to anion:

2. Reorientation of the protonated anion:

3. A proton jump to a neighboring anion:

This theory was supported by the fact that the conductivity of AP crystals increased proportionally to the concentration of an added proton donor impurity, such as HSO_4^- ions. At the same time, the activation energy decreased. The mobility of protons in the AP lattice is

$$\mu = 20 \exp\left(-0.81 \frac{\text{eV}}{kT}\right),$$

where μ is the ion mobility in $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$ and T is the temperature in kelvin. The dielectric relaxation of AP crystals has been investigated. Values of the activation energy for the ion mobility and for the time of dielectric relaxation were very similar. There is a close relationship between electrical conductivity and thermal decomposition of AP. The activation energies for the overall rate of LTD $E_t = 142 \pm 6.7 \text{ kJ/mol}$ ($33.9 \pm 1.6 \text{ kcal/mol}$) and the rate of nucleation growth $E_g = 146 \pm 21 \text{ kJ/mol}$ ($35 \pm 5 \text{ kcal/mol}$) are very similar. Consequently, the processes of nucleation growth determine the total rate of thermal decomposition of AP.

The electrical conductivity of single crystals of AP was measured between 298 and 453 K (25 to 180 °C) [167, 168]. Plots of $\log \sigma T$ versus $1/T$ revealed two linear regions, one from 298 to 373 K (25 to 100 °C) and another from 373 to 453 K (100 to 180 °C). Activation energies for the conduction processes in the low- and high-temperature regions were 0.12 and 1.04 eV, respectively. The electric conduction is a bulk process and not a surface mechanism. Conduction in the low-temperature region is predominantly due to the migration of protons and is sensitive to the concentration of interstitial H_2O molecules which act as proton donor and acceptor sites. In the high-temperature region, conduction is due to migration of NH_4^+ through cation vacancies. The low-temperature activation energy presumably represents the potential barrier for the migration of protons and the high-temperature activation energy the barrier for the migration of NH_4^+ ions. The conductivity is sensitive to the interstitial H_2O concentration in the low-temperature region and to the cation vacancy concentration in the

high-temperature region. Similar measurements were made for doped crystals containing various quantities of Mg^{2+} , Cu^{2+} , Ca^{2+} , Sr^{2+} , or SO_4^{2-} ions. The conductivity of doped crystals was a function of the ion radius of the cation impurity.

The electrical conductivity of AP undergoing thermal decomposition was increased by doping the AP crystals with SO_4^{2-} ions [169]. The enthalpy for migration of defects was 0.8 eV and the enthalpy for formation of defects was 1.2 eV. The defect structure of AP is of the Schottky type and the major charge-carrying ion is ClO_4^- .

A mechanism of proton conductivity was proposed by Hor and Jacobs [170, 171]. The DC electrical conductivity of pure and doped AP single crystals was measured in two different crystal orientations, with the electric field applied perpendicularly to either (001) or (210) planes. The conductivity along the direction of the *c*-axis was found to be lower than that normal to (210) by a factor of five to ten. The DC electrical conductivity of AP was decreased by Pb^{2+} ions but increased by SO_4^{2-} and CrO_4^{2-} ions. The DC conductivity of AP crystals was enhanced by doping with CrO_4^{2-} so that charge transport by defects introduced by the CrO_4^{2-} ions is inferred [172]. Exposure to ammonia enhanced the conductivity of pure AP. A proton conduction mechanism was proposed that takes due regard of the structure of AP. The effect of the various additives on the conductivity are attributed to their influences on the formation of charge-carrying protons.

Electrical conductivity of burning AP pellets with rectangular cross-sections can be used as a diagnostic tool to measure the progression of the flame front. Rectangular slabs (compressed to a density of 1.93 g/cm^3 , dimensions 10×10 , 12×12 , $12 \times L$, $L = 2.7\text{--}8 \text{ mm}$) were mounted between Zn or Pb electrodes attached to opposite faces. The conductivity was recorded as a function of time after the pellet was ignited from one end [173]. For the stable combustion region, an attempt was made to explain the pressure dependence of electrical conductivity in terms of an increase in surface temperature in accordance with the conductivity mechanism of liquid ionic salts.

It was assumed that proton conductivity is realized due to the formation of a complex N_2H_7^+ between the ammonia molecule located in the interstitial space and one of the ammonium ions surrounding it [174].

If the potential across an AP crystal is increased to the point of electrical breakdown, the crystal will ignite and explode [175, 176]. The electric strength of AP depends on the density, the thickness of pressed pellets, the duration (τ) of the pulse front edge of the high voltage, and the dose of γ -pre-irradiation (if any). The electric breakdown of both irradiated and unirradiated pressed AP pellets follows the path of air pores. At $\tau < 2 \mu\text{s}$, the increase in the irradiation dose causes an increase in the electric strength of AP tablets. However, at $\tau > 5 \mu\text{s}$ it causes a decrease in the electric strength of the AP pellets. This may be connected with the AP decomposition during irradiation and the time of the electric pulse action. During the radiation chemical decomposition, the thickness of the near-surface layer and its physical and chemical properties change. This has an effect on the breakdown voltage of AP. With long voltage pulses, the burning out of a through-channel takes place and it ends in electric breakdown of the dielectric.

3.6.1 Other Aspects of Electrical Conductivity

In the preceding sections we were mostly interested in electrical conductivity, how it may be affected by dopants, and how changes in electrical conductivity may relate to changes in crystal structure, thermal stability, and burning rate. A totally different aspect is the use of AP (besides many other ionic salts) as a dopant for proton-conducting solid polymer polyethylene oxide (PEO). The protons in the NH_4^+ ion have sufficient mobility to make polymer films electrically conductive [177–179]. AP is soluble in polyethylene oxide. The NH_4ClO_4 solution in PEO and the solution-cast film made therefrom is sometimes called a [complex] but it is not a complex in the sense of inorganic chemistry. The solubility of NH_4ClO_4 in PEO is limited to a maximum concentration NH_4^+/EO ratio of 0.167 (which is safe because otherwise this would be a rocket propellant). The highest conductivity (approximately $1.05 \times 10^{-5} \text{ S cm}^{-1}$) is for a film with an NH_4^+/EO ratio of 0.02–0.1. Proton-conducting solid polymer electrolytes can be used in novel lightweight ion batteries.

3.7 Permittivity (Dielectric Constant) of Ammonium Perchlorate

The permittivity (dielectric constant) of AP was measured in a frequency range between 100 to 10000 Hz and is equal to 5.1 ± 0.3 [180]. It was shown that the values of conductivity of AP obtained directly from these measurements coincide with those calculated using the tangent of the loss angle.

AP, AN, and organic explosives can be ignited by heating with microwaves at $2450 \pm 50 \text{ MHz}$ [181].

3.8 Magnetic Properties of Ammonium Perchlorate

Nuclear magnetic resonance (NMR) spectra of AP revealed that both the ammonium and perchlorate ions can rotate freely [182]. The second moments of the proton resonance absorption line in polycrystalline NH_4ClO_4 were found to be $1.27 \pm 0.02 \text{ gauss}^2$ at 70 K and $1.18 \pm 0.01 \text{ gauss}^2$ at 298 K. These results were interpreted in terms of reorientation of the ammonium ion using random or nearly random axes. Spin-lattice relaxation times for polycrystalline NH_4ClO_4 have been measured as between 77 and 298 K by a progressive saturation method. These relaxation times are consistent with a barrier hindering reorientation of $2.0 \pm 0.6 \text{ kcal}$. Both ions were found to rotate in the cubic structure while only ammonium does in the orthorhombic one. The molar magnetic susceptibility of AP is 46.3×10^6 .

The proton spin-lattice relaxation, second moment, and magnetization of NH_4ClO_4 were investigated between 1.5 and 100 K using pulse NMR techniques [183]. The data was interpreted with reference to the possible hindered rotor levels of the NH_4^+ ion.

Nuclear magnetic resonance spectra of AP crystals between 1.3 and 50 K and relaxation experiments revealed that an increase in the proton second moment from its high-temperature value of $\sim 1.18 \text{ G}^2$ to the value of 4.30 G^2 below 4.2 K was associated with a characteristic activation energy of $\sim 4 \times 10^{-21} \text{ J/molecule}$ ($\sim 0.6 \text{ kcal/mol}$) [184]. No evidence could be found for nuclear spin conversion between the symmetry species of the ammonium ion from measurements of the static proton magnetic susceptibility above 1.3 K. Measurements of the proton relaxation times T_1 and $T_{1\rho}$ agreed with previous findings from others regarding NH_4ClO_4 and were similar to observations on other ammonium compounds having low reorientation barriers.

The spin-lattice relaxation time of the dipolar energy T_{1D} and the characteristic time T_{SD} for the spin diffusion between NH_4^+ ions of different librational symmetry species were measured as functions of temperature and crystal orientation in NH_4ClO_4 [185]. The graph displaying the T_{1D} versus temperature function showed shoulders around 44 and 28 K related to the librational tunneling frequency and the proton resonance frequency, respectively. A broad minimum around 10 K is believed to correspond to the linewidth transition. The characteristic time T_{SD} is less than 0.5 ms above 4 K, showing that the ammonium protons in different symmetry species have, at least locally, a common spin temperature during the magnetization recovery.

A study of the spin-lattice relaxation of protons in NH_4ClO_4 at low temperatures revealed that the NH_4 librational tunneling determines the spin-librational wave functions, which are derived first [186]. The dominant transition rates related to the magnetic dipolar interaction between the NH_4 protons reproduce the angular dependence of the proton relaxation time well. When all the transition rates were taken into account, both the temperature and frequency dependence of the relaxation rate aligned with existing experimental data for a powder sample of AP.

Measurements of an AP sample in a DC superconducting quantum interference device in zero field at 4.2 K revealed unexpected magnetic moment oscillations at 1.5 kHz [187]. A computation of the magnetic fields suggested that the proton nuclear magnetic resonance may explain the measured resonance (considering reorientation of the ammonium group by quantum tunneling of protons and a magnetic proton dipole-dipole intermolecular interaction model).

3.9 Crystal Morphology and Mechanical Properties of Ammonium Perchlorate Single Crystals

The crystal faces on AP single crystals behave quite differently when it comes to thermal decomposition or etching with a solvent. Some of the etch pits on the cleavage surfaces were found to be distributed randomly while others were clearly aligned in specific crystal directions. Strained crystals exhibited slip bands. Moreover, the various possible systems were deduced by computing from the crystal structure, the most

likely low-index slip planes, and slip directions also, which are consistent with the observed etch pit alignments and slip bands.

Cleavage and growth faces of AP single crystals have been examined by high-power interference-contrast microscopy [188]. From the observed directions of etch-pit arrays on three crystallographically distinct faces of the orthorhombic form of AP, and from the nature of the slip bands on deliberately deformed crystals also, the nature of the dislocations present have been clarified. All the observed alignments and bands on the various faces may be accounted for in terms of dislocation movement on $(20\bar{1})$, (201) , (401) , $(40\bar{1})$, (110) , $(\bar{1}10)$, (010) , and (001) planes. Preferential evaporation occurred from dislocation cores emergent at (001) faces.

The formation of etch pits on the cleavage surfaces of AP single crystals has been studied by optical and electron microscopy [189]. Ethyl and butyl alcohols and their mixtures were the most satisfactory etchants. Well-defined etch pits could not be detected on the c face, which dissolved very rapidly. Numerous round etch pits then appeared followed by elongated and roughly parallel curved channels which finally became connected. This left nearly circular flat-topped 'hills' with clearly delineated terraced sides. However, when the crystals were etched in butyl alcohol, well-defined rectangular pits were formed on the m face, with either a 3:1 or 4:1 length-to-width ratio. They resembled elongated stepped or terraced pyramids and were always orientated with their long sides parallel to the $[001]$ direction.

Surprisingly, co-crystallizing AP whiskers with potassium permanganate additions not only increases the burning rate but also improves mechanical strength and elasticity of such crystals [190]. Such whiskers were grown up to a length of 50 mm in humid conditions promoting creep.

The laser-Brillouin scattering method was used for the determination of the elastic and elasto-optic constants of AP crystals at room temperature [191]. One of its advantages over the ultrasonic technique is that the usual boundary conditions required by the latter are relaxed. However, it is suitable only for transparent crystals. The elastic and elasto-optic constants may be used to predict the dynamical behavior of ions and molecules in a crystal. The polarized Brillouin scattering spectra yielded nine elastic constants as well as the absolute value of nine elasto-optic constants.

The fracturing behavior of AP is of interest for the grinding of AP powder and the friction and impact sensitivity of anything containing AP. Diamond pyramid (Vickers) micro-indentation hardness testing was used to examine the plastic deformation and cracking behaviors of single crystal AP. Using polarized light microscopy, it was determined that the strain field caused by edge dislocations surrounding the hardness impression was rather far-reaching. In a separate series of tests, single crystals placed in a mineral oil bath were shocked by exploding a detonator. High-speed photography was used to observe the crystal response to the shock wave and samples were recovered for quantitative chemical analysis of decomposition products [192–194]. Traces of slip planes and cracks formed at hardness indentations on (210) and (001) surfaces were examined under the microscope. In the vicinity of the diamond impact, residual

strains were found to extend beyond crack tips. Similar residual strains exist in freshly ground AP and may heal with time.

An ultra-high-vacuum (UHV) atomic force microscope (AFM) was used to study AP surfaces at room temperature and atmospheric pressure down to 10^{-9} mm Hg vacuum [195, 196]. Because AP is hygroscopic, special precautions in sample handling were necessary. Atomic force microscopy studies of the (210) plane of AP revealed several interesting surface artifacts induced by the scanning tip, although the applied force was less than 30 nN. Nano-scale surface sensitization may have been caused by the scanning tip during repeated raster scanning while tip-sample contact was maintained. A roughening pattern may have been formed when the surface was exposed to moisture. Identification of features was difficult due to the large unit cell of this salt (40 atoms / unit cell). AP crystals were immersed in mineral oil with the (210) surface 6.0 mm from a detonator. When fired, the detonator delivered a 24.4-kbar shock, corresponding to the reaction threshold for that crystal orientation. High-speed photographs revealed luminosity near some of the hardness impressions. The photographs also revealed the occurrence of the same slip deformation identified previously from hardness testing. The shocked crystal was recovered intact and cleaved twice through Vickers impressions on the (001) and shock-entry (210) surfaces, allowing spatial chemical analysis of the interior regions of the crystal using X-ray photoelectron spectroscopy (XPS). Along these freshly cleaved surfaces, the XPS results revealed enhanced perchlorate decomposition as a result of the impressions. The greatest decomposition was not immediately adjacent to the impressions but near the tips of cracks and along slip planes that extended from these impressions by at least several millimeters [197].

3.10 Thermodynamic Properties of Ammonium Perchlorate

The heat capacity, enthalpy of formation, and entropy of formation can be calculated from the polynomial Shomate equations based on data curve fitted by NIST and posted on the Webbook website:

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

$$H^\circ - H^\circ_{298.15} = A\tau + B\frac{\tau^2}{2} + C\frac{\tau^3}{3} + D\frac{\tau^4}{4} - \frac{E}{\tau} + F - H$$

$$S^\circ = A \ln(\tau) + B\tau + C\frac{\tau^2}{2} + D\frac{\tau^3}{3} - E/(2\tau^2) + G$$

where A through H are constants, C_p = heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$, H° = standard enthalpy in kJ/mol, S° = standard entropy in $\text{J mol}^{-1} \text{K}^{-1}$, and τ = temperature K/1000. The constants A through H are listed in Table 5 for two temperature regimes below and above the phase change at 513 K.

Table 5: Shomate equation constants for AP.

Temperature range, K	298–513	513–1000
A	49.81390	225.2150
B	297.3000	–203.0560
C	–186.1620	402.2310
D	128.3380	–137.7330
E	0.245965	–7.484290
F	–321.6170	–373.0730
G	164.3460	476.7260
H	–295.7670	–295.7670

Data source: [198].

3.10.1 Heat Capacity of AP

Heat capacity data used by [151] were derived from the thermal diffusivity α of AP for the range from 293 to 487 K (20 to 214 °C) and can be described by the linear equation

$$C_p = 0.251 + 4.076 \times 10^{-4}t,$$

where C_p is the heat capacity in $\text{cal g}^{-1} \text{°C}^{-1}$ and t is the temperature in °C. This calculates into a heat capacity of $1.093 \text{ J g}^{-1} \text{K}^{-1} = 0.261 \text{ cal g}^{-1} \text{°C}^{-1}$ at 298 K. The same authors obtained and listed similar data for a wide range of other oxidizers, binders, and solid propellants. The heat capacity of AP has been measured repeatedly but the measured data does not always agree. Average data in existing research for temperatures below 513 K are $1.29 \text{ J g}^{-1} \text{K}^{-1}$ ($0.309 \text{ cal g}^{-1} \text{°C}^{-1}$) and $1.527 \text{ J g}^{-1} \text{K}^{-1}$ ($0.365 \text{ cal g}^{-1} \text{°C}^{-1}$) for temperatures above 513 K.

The heat capacity of AP was determined by adiabatic calorimetry from 5–350 K and found to be of simple sigmate character without thermal anomalies. The heat capacity (C_p), entropy (S°), enthalpy function $(H^\circ - H^\circ_0)/T$, and Gibbs energy function $(G^\circ - G^\circ_0)/T$ evaluated at 298.15 K from these data were 30.61, 44.02, 20.24, and $-23.78 \text{ cal mol}^{-1} \text{K}^{-1}$, respectively [199]. The heat capacity of AP and two other perchlorates is shown in Figure 13. This figure combines two curves in one chart. The lower right portion of this split chart is an enlarged view of the lower left corner of the chart.

The heat capacity of AP is a function of the degree of freedom of free rotation of the ammonium ion and changes at the point of phase transition. There is a very low rotational barrier of the NH_4 groups in NH_4ClO_4 that shows up in NMR spectra [200].

The specific heats of AP, RDX, and HMX were measured at room temperature all the way up to the decomposition temperature region by use of a laser flash method [149]. The specific heats of AP, RDX, and HMX as a function of temperature are graphed in Figure 14.

Figure 13: Heat capacities of NH_4ClO_4 , KClO_4 , and CsClO_4 . (Republished and modified from [199], with the permission of © 1969 American Institute of Physics; permission conveyed through Copyright Clearance Center, Inc.)

Figure 14: Heat capacities of AP, RDX, and HMX. (Republished and modified from [149], with permission from © 1985 Old City Publishing, granted by Dr. Ian Mellanby 10 May 2021.)

Other sources for heat capacity produced C_p at 298 K = 128.072 J mol⁻¹ K⁻¹ [201]. The equation for AP in the NIST Chemistry WebBook gives a heat capacity of 128.04 J mol⁻¹ K⁻¹ at 298 K [202].

3.10.2 Heat of Fusion and of Sublimation of AP

A heat of melting of 251 J/g (60 cal/g) and a melting point of 820 K were used for calculations of surface burning processes in AP [203]. The heat of sublimation of AP can be calculated from the vapor pressure curve and is estimated to be 243 kJ/mol (58 ± 2 kcal/mol) [128, 129]. The equilibrium gas pressure over the AP solid surface was measured. The temperature dependence of gases over solid AP allows the calculation of a dissociation enthalpy ($H_{\text{diss}} = 240.6 \text{ kJ/mol} = 57.5 \text{ kcal/mol}$). H_{diss} of a salt can also be calculated from the enthalpies of formation from salt and from gaseous bases and acids. This calculation for AP gives 241.8 kJ/mol (57.8 kcal/mol), which is in good agreement with results obtained from the surface temperature-pressure dependence. It also conforms with mechanisms of the gasification of salt through dissociation reactions. Values of enthalpy from 238 to 251 kJ/mol (57–60 kcal/mol) for AP dissociation have been obtained in many other studies. One must remember that one molecule of the salt produces two molecules of gas rather than one. The AP dissociation enthalpy so often has been erroneously taken as the activation energy of AP decomposition, with dissociation processes described as a reaction characterized by kinetic parameters.

3.10.3 Enthalpy of Formation of AP

The enthalpies of formation of the orthorhombic (low temperature) and cubic (high temperature) modification of AP differ by 9.6 kJ/mol (2.3 kcal/mol) [109]. The enthalpy of transition measured in this way is +9.6 kJ/mol (2.3 ± 0.2 kcal/mol). Other sources give the phase change enthalpy as 11.3 kJ/mol (2.7 kcal/mol) [204, 205]. The transition from orthorhombic to cubic is endothermic. The energy required for converting orthorhombic phase AP to cubic phase AP is only 9.6 kJ/mol (2.3 kcal/mol). If the modification is not stated for thermodynamic data at 298 K, one may assume that data is for the orthorhombic modification. Literature data for the enthalpy of formation of AP is summarized in Table 6.

The most reliable thermophysical data are assumed to be those posted at the NIST WebBook website. However, the enthalpy of formation recommended by NIST is $\Delta_f H^\circ_{\text{solid}} = -295.77 \text{ kJ/mol}$ based on fairly old data from Chase [198] that was last reviewed in December 1962. Obviously, these numbers require a thorough re-examination in view of more recent data.

The enthalpy of dissolution of AP was measured on a precise swinging solution calorimeter [210]. The most reliable value of the formation enthalpy of AP was derived on the basis of the selected value of the anion formation enthalpy and measured value of the salt dissolution enthalpy.

AP $M = 117.489 \text{ g/mol} = 8.5114 \text{ mol/kg}$.

Heat capacity, enthalpy of formation and free energy of formation AP and ADN were predicted using DFT calculations but the agreement with experimental data was only very poor, with predicted heat capacity much higher than measured values [211]. The data indicated that ADN decomposes more readily than AP.

The enthalpy of formation of solid NH_4ClO_3 , an unstable chemical and a common contaminant in AP, is $-272 \text{ kJ/mol} = -65.1 \text{ kcal/mol}$.

3.10.4 Entropy of Formation of AP

Literature data for the standard entropy of formation of solid AP are listed in Table 7.

Table 7: Literature data for the standard entropy of formation of solid AP.

Entropy of formation ΔS_{298}^f		References
$\text{J mol}^{-1} \text{K}^{-1}$	$\text{cal mol}^{-1} \text{°C}^{-1}$	
184.18		[202]
184.180		[201]

The ionic entropy of the ClO_4^- ion can be derived from the enthalpy of solution of NH_4ClO_4 (0.80 kcal/mol), the mean activity coefficient of NH_4ClO_4 ($\gamma = 0.394$), the solubility of NH_4ClO_4 ($m = 2.12$), and the ionic entropy of $\{\text{NH}_4\}^+$ ion $S_0^{298}[\text{NH}_4^+(\text{aq})] = 27.1 \text{ cal mol}^{-1} \text{K}^{-1}$. The entropy of solution of NH_4ClO_4 is $26.1 \text{ cal mol}^{-1} \text{K}^{-1}$ from the above data. This leads to a standard ionic entropy for aqueous ClO_4^- ion of $43.0 \pm 0.2 \text{ cal mol}^{-1} \text{K}^{-1}$ [199]. Wagman et al. reported $43.5 \text{ cal mol}^{-1} \text{K}^{-1}$ for this property [212].

3.11 Molecular Structure of Ammonium Perchlorate

It was suggested that, on the basis of qualitative changes in unindexed powder diffractometer patterns, both NH_4ClO_4 and isostructural NH_4BF_4 should undergo polymorphic transitions near 83 K. Neither the heat capacity work of Westrum and Justice [199] on NH_4ClO_4 nor that of others supported this contention.

3.11.1 Crystal Structure of AP

AP crystallizes in an orthorhombic $Pna2_1$ space group and contains four molecules per unit cell. Each perchlorate ion is surrounded by seven ammonium ions and vice-versa.

Early XRD studies suggested an ordered hydrogen-bonded arrangement of the ions but this arrangement was not consistent with the overwhelming evidence from IR [213], electron proton resonance (EPR) [214], NMR [182], slow neutron data [215], and neutron diffraction data [216]. This suggested free rotation of the ammonium ion at room temperature. An IR study by Ibers [182] indicated reorientation of ions in AP at temperatures as low as 77 K with an activation energy of 2.0 ± 0.60 kcal/mol. Ibers predicted a line-width transition between 45 K and 55 K. However, experiments have been performed with temperatures as low as 20 K with no evidence of a line-width transition. A value of 0.55 ± 0.05 kcal/mol was obtained for the potential barrier of reorientation from the hyperfine splitting in the EPR spectrum, based on examining the ion radical $\cdot\text{NH}_3^+$ in single crystals of AP at temperatures of 75 K to 293 K.

A computer simulation of crystal defects in AP was essentially a modification of an earlier crystal defect program [217, 218]. This program had evolved gradually over a period of ten years. It was initially developed for determining defect properties in alkali halides with NaCl type structures. Later, it was extended to include the complex ion cubic crystal modification of AP. Based on the numerical results, a vacancy migration turnstile mechanism was proposed to account for the DC electrical conductivity of AP. By and large, these theoretical calculations agreed with the experimental work of Maycock, i.e., the activation energies for migration of a vacancy and the energy of formation of the Schottky defect were found to be 20% lower than those reported by Maycock.

A neutron diffraction study of AP concluded that orientation of ammonium ion is a highly disordered one, with the ion undergoing a free or nearly free rotation [216]. A rotating ammonium ion is also supported using IR spectra [213], heat capacity studies between five and 350 K [199], cold neutron scattering cross section studies [215, 219, 220], and NMR studies at low temperatures [182]. The second moments of the proton resonance absorption line in polycrystalline NH_4ClO_4 were found to be 1.27 ± 0.02 gauss² at 70 K and 1.18 ± 0.01 gauss² at 298 K. These results were interpreted in terms of reorientation of the ammonium ion around random or nearly random axes. Spin-lattice relaxation times for polycrystalline NH_4ClO_4 were measured between 77 and 298 K by the progressive saturation method. These relaxation times indicated a reorientation barrier of 8.368 ± 2.5 kJ (2.0 ± 0.6 kcal).

The crystal structure of AP was studied at 298, 78, and 10 K by means of neutron diffraction [221]. The NH_4ClO_4 crystal has an orthorhombic unit cell, space group *Pnma*, with four formula units per cell at all three temperatures. The unit cell dimensions at 298 K are $a = 9.20$, $b = 5.82$, $c = 7.45$ Å, as determined previously; at 78 K, $a = 9.02$, $b = 5.85$, $c = 7.39$ Å; and $a = 8.94$, $b = 5.89$, $c = 7.30$ for 10 K. Initial positions of H atoms were determined from a difference Fourier map of the room temperature data. Each ammonium group is surrounded by ten oxygen atoms with short N—O distances ranging from 2.9 to 3.25 Å. The ClO_4^- group and NH_4^+ group each have essentially ideal tetrahedral structure. They are linked together by N—H...O type hydrogen bonds; one for each hydrogen to form a three-dimensional network. Examination of the rms amplitudes for libration and the hydrogen bonding of the NH_4^+ ions indicated that two of the four hydrogens were bound identically, one hydrogen was bound more rigidly, and the fourth more weakly. These results suggested that the rotational motions of the ammoniums are quite complex even at 10 K.

The crystal structure of AP had been assigned to the orthorhombic space group *Pnma*. With the availability of improved instruments and computing capability, the structure of AP has been re-examined several times and earlier discrepancies were resolved. Since only two-dimensional X-ray or neutron diffraction data had been used until 1975 for the crystal structure determination of AP, a redetermination of AP structure by three-dimensional X-ray counter data produced the following cell parameters: $a = 9.227$, $b = 7.454$, $c = 5.819$ Å (24 °C), $Z = 4$, space group *Pna2*₁ [222]. The previously proposed space group, *Pnma* (which was used for the two-dimensional analysis), did not allow a three-dimensional refinement. The ammonium ion does not have a completely free rotation.

The structure of AP at 298 K has been refined, starting with the same XRD data of Peyronel and Pignedoli [222], although it took a different mathematical approach [223]. A satisfactory refinement was achieved in space group *Pnma*, which was in agreement with earlier observations at low temperatures. It clearly demonstrated that *Pnma* is the correct space group for room-temperature NH_4ClO_4 , just as it is at lower temperatures. The observed bond lengths, Cl—O(1) = 1.432, Cl—O(2) = 1.424, Cl—O(3) = 1.442 Å, are (within one standard deviation) the same as those of Peyronel and Pignedoli [222]. This was obtained with the positions of the ammonium ions held fixed.

The orthorhombic phase of AP was investigated by XRD below room temperature [224]. The temperature dependence of lattice constants revealed anomalous behavior around 200 and 100 K. The length of the *b*-axis steeply increased as temperature decreased, especially when below 100 K. The crystal structure in the orthorhombic phase was then refined at 300, 250, 200, 150, 120, 100, and 80 K. The parameters essentially agreed with the results of Choi, Prask, and Prince [221].

The effect of pressure up to 5.6 GPa on the structure of AP was investigated at room temperature using XRD, IR, and Raman spectroscopy [225, 226]. New peaks were also observed in the XRD pattern above 0.9 GPa and could not be indexed to the orthorhombic structure. The intensities of these new peaks increased up to 2.9 GPa. However,

when above 3.0 GPa all of the peaks observed at lower pressures disappeared completely and a new set of peaks appeared that persisted up to 5.6 GPa, which was the limit of the study.

Two phase transitions were observed. Under hydrostatic conditions, the first transition started at about 0.9 GPa, with the appearance of a few new diffraction peaks and a discontinuity in the pressure-induced shifts of certain Raman frequencies. This transition is most likely a molecular change in AP due to the [freezing] of freely rotating NH_4 units, which is similar to effects seen at low temperatures. The second transition started at 2.9 GPa with a drop in diffraction intensity followed by a new pattern of diffraction peaks by 3.0 GPa. This transition was also characterized by another discontinuity in the Raman shifts and the emergence of two new Raman modes. The phase above 3.0 GPa was stable to 5.6 GPa. The P - V data to 0.9 GPa obtained from XRD measurements were used to calculate a bulk modulus of 15.2 ± 0.3 GPa for the ambient-pressure phase of AP (see [227]).

3.11.2 Computational Chemistry of the Molecular Structure of AP

The electronic structure, vibrational properties, absorption spectra, and thermodynamic properties of crystalline AP and ADN were compared using DFT in the local density approximation [211]. The results revealed that the p states for the two solids play a very important role in their chemical reactions. From the low frequency to high frequency region, ADN has more degrees of freedom of motion modes for the vibrational frequencies than AP. The absorption spectra of AP and ADN display a few strong bands in the fundamental absorption region. The thermodynamic properties revealed that ADN is easier to decompose than AP as the temperature increases. Calculated AP crystal lattice parameters were very close to those measured by Peyronel and Pignedoli [222].

AP that is subjected to sudden compression may detonate. The compressibility and phase change behavior of AP crystals at very high pressures are, therefore, important for modeling detonation processes in AP. DFT can be used to predict the hydrostatic compression of crystalline AP and the compressibility of AP crystals at very high pressures [228].

The structures and energy levels of AP and different aggregates formed by AP with one or two water molecules in both gaseous and condensed phases were calculated at the B3LYP/6-311G(3df,2p) level using a polarizable continuum model (PCM) method [229]. The results revealed that, for the gaseous dissociation processes, the main dissociation channel is

with dissociation energies of 61.5, 78.7, and 82 kJ/mol (14.7, 18.8, and 19.6 kcal/mol), respectively. The formation of $n\text{H}_2\text{O} \bullet \text{ClO}_4 \bullet \text{NH}_4$ ($n = 0, 1, 2$) ion pairs is not favored energetically because the dissociation energies are 462, 479, and 489 kJ/mol (110.5, 114.4,

and 116.9 kcal/mol) for $n = 0, 1, 2$, respectively. In aqueous solution, AP and its aggregates mainly dissociate into ion pairs, reflecting the important effect of solvation. The solvation free energy predicted with PCM for the isolated AP (−30.0 kcal/mol) is consistent with the average values determined from the aggregates of AP with one H₂O (−30.2 kcal/mol) and 2H₂O (−30.0 kcal/mol), respectively. These values indicate that the PCM method can accurately predict effects of hydrogen bonding between the solvent (H₂O) and the solvate (NH₄ClO₄) on the solvation energies.

The crystal structure of AP was computed using a DFT method [230]. The energy band structure, density of energy states, electron population, and charge density of AP were analyzed and demonstrated that AP is an insulator with a band gap of 5.517 eV. The conduction bands of AP are mainly composed of O-2p and Cl-3p orbits and the valence bands are composed of atomic (ionic) orbitals in the crystal. The structure of AP is that of a typical ionic crystal. Weak hydrogen bonds N—H···O exist in the crystal.

The optical properties of NH₄ClO₄ crystals, including dielectric function, refractive coefficients, absorption spectra, and reflection spectra were calculated by a first-principle method based on DFT [231]. The relationship between peaks in the dielectric function curves and the inter-bands transitions in the band structures were analyzed. Computational results demonstrated that the static dielectric function should be 1.10, the static reflectivity n_0 should be 1.05, and the maximum absorption coefficient should be $1.91 \times 10^5 \text{ cm}^{-1}$ corresponding to a peak energy of 10.88 eV, in agreement with existing experimental results. The response function explains electron density distribution throughout the AP crystal lattice [232].

3.12 Optical Properties of Ammonium Perchlorate

3.12.1 IR Spectra of AP

An IR, Raman, and XRD study of NH₄ClO₄ was conducted in the temperature ranges 300 to 17 K, 300 to 130 K, and 300 to 120 K, respectively. This was to determine the effects of low temperature on the rotational behavior of the ammonium ion, to search for evidence of hydrogen bonding, and to determine whether low-temperature phase transitions exist between 300 and 120 K [233]. The infrared studies also included the deuterated salt. The ammonium ion rotated with relatively little hindrance in NH₄ClO₄ at room temperature. Changes in the IR spectra, as well as intensity measurements of the vibrational bands indicated anomalous behavior in the region 100 to 110 K as well as 17 to 50 K (see Figure 15).

Infrared, Raman, and XRD data conclusively demonstrated that no phase change occurs in AP from 300 to 120 K. A phase change at 100 to 110 K, corresponding to the 173 K change in the isomorphous NH₄BF₄ salt, was tentatively proposed but could not be proven. Some evidence of distortion of the ammonium tetrahedron at temperatures below 50 K was found. There were strong indications of hydrogen bonding below 20 K and weaker hydrogen bonding between 50 and 20 K.

Figure 15: Infrared spectrum of NH_4ClO_4 at room temperature (bottom) and at 17 K (top). (Republished and modified from [233], with the permission of © 1972 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center).

There was no source given for the IR spectrum posted on the NIST Webbook website but we are presenting it here nevertheless in the hope that we can find a better quality spectrum of more recent provenience. This spectrum has contamination due to oil around 2900 and 1380 cm^{-1} and is marked with an asterisk in Figure 16.

Figure 16: Infrared spectrum of NH_4ClO_4 . (Reproduced and modified with permission from [234].)

The spectral transmittance of large single crystals of normal AP and deuterated AP grown from aqueous solutions has been measured in the ultraviolet (UV), visible, near-IR, and IR regions of the spectrum [235]. The crystals were transparent in the visible region and throughout much of the UV region. The absorption edge of both the deuterated and undeuterated crystals was in the UV region near 200 nm. There were strong absorption bands in the near-IR and IR regions. The absorption was so

strong that the instrument bottomed out and no details of the absorption bands were revealed. From the intensity of an absorption band at $1.55\ \mu\text{m}$, the mol-percent ^1H in the deuterated AP crystals was estimated to be 1.1%.

An infrared study by Brill and Goetz [121] noted the disappearance of the band at $939\ \text{cm}^{-1}$ associated with the ν_1 mode of the ClO_4^- group at pressures between 1.0–2.4 Gpa. They tentatively assigned this to the orthorhombic to cubic transition.

Molecular motion of the ammonium ion has been investigated by IR spectroscopy in a series of ammonium salts which were known to be weakly hydrogen-bonded. Infrared spectra of the isotopically isolated NH_3D^+ ion in NH_4ClO_4 and NH_4BF_4 were recorded as being between 295 and 22 K [236]. The absorption in the N–D stretching region of the NH_3D^+ ion consisted of two broad bands centered at 2425 and $2399\ \text{cm}^{-1}$ with approximate half-widths of 20 and $30\ \text{cm}^{-1}$, respectively, at 22 K. The broadness of the bands has been attributed to rapid reorientation of the NH_3D^+ ammonium ions and the consequent short lifetime of the upper vibrational state. The band broadening persists down to the lowest temperature. No significant lifetime broadening has been found in the spectra of the NH_3D^+ ion in other salts.

The IR spectra of the ND-stretching bands of dilute NH_3D^+ in NH_4ClO_4 measured over the temperature range from 3 K to room temperature revealed that, at low temperatures, the NH_3D^+ is preferentially oriented [237]. The extent of the orientation at a given temperature depends on the deuterium concentration, and thus on the concentration of NH_3D^+ ions. As the temperature is raised, the various N–D stretching bands collapse due to a variety of dephasing processes.

The isotope effect, which is visible if one or more hydrogens are replaced by deuterium, depends on the location of the N–D bond in the crystal lattice. The N–D stretching region of the IR of deuterium-doped NH_4ClO_4 indicates the existence of subtle energy differences [238]. The N–H spectrum in ND_4ClO_4 was also examined. Comparison of the two sets of spectra led to an explanation of the small energy differences as due to tunneling among the distinct positions the NX_3Y^+ ions can assume in the lattice. The distinct orientations of NH_3D^+ and the ND_3H^+ ions have slightly different energies and this, along with the impact of tunneling, accounts for all the eight observed lines.

IR spectra of AP was predicted using DFT calculations in the local density approximation and was compared to experimental spectra as well as those obtained for ADN [211]. The lattice mode spectra of AP and ADN display similar features in the region $28\text{--}220\ \text{cm}^{-1}$. AP has seven frequencies in this region, all of which are in good agreement with existing experimental findings [106]. AP has four frequencies in the region of $400\text{--}700\ \text{cm}^{-1}$. The molecular motion of the first frequency is the symmetric bending of ClO_4 . The associated motions corresponding to the following frequencies are concentrated in the asymmetric bending of ClO_4 . Similarly, ADN also has four frequencies which do not appear in AP. This is due to these corresponding to the asymmetric bending of $\text{N}(\text{NO}_2)_2$. AP has five frequencies in the region of $1000\text{--}1200\ \text{cm}^{-1}$. The molecular motions of the first two frequencies are the symmetric stretching of

ClO_4 , and the motions corresponding to the following frequencies are the asymmetric bending of ClO_4 . Calculated frequencies for AP in this region [211] had large deviations from corresponding existing experimental values. The motions of these frequencies are concentrated in the ClO_4 moieties, thus this discrepancy may be due to intermolecular hydrogen bonding interactions present in the crystal lattice which are not well described by DFT. The motion modes of NH_4 in AP and ADN present similar features in the region of $1400\text{--}3300\text{ cm}^{-1}$. The motion of the first frequency involves the asymmetric bending of NH_4 , whereas those of the next two frequencies are concentrated in the symmetric and asymmetric stretching of NH_4 , respectively.

3.12.2 UV Spectra of AP

Irradiation of AP crystals with UV light produces an effect similar to the effect of X-rays or γ -rays [239]. The action of light, which is similar to the action of ionizing radiation, is mainly restricted to the induction period.

Color centers absorbing at 610, 295, and 360 nm were formed in AP crystals irradiated with UV light of $2537\text{ \AA}$ [240]. Thermal bleaching overnight at room temperature destroyed the 610-nm band with no apparent change in the 295 and 360-nm bands. Further thermal bleaching for two weeks resulted in the formation of a new band at 500 nm and elimination of the 360-nm band. Bleaching of the 610-nm band at room temperature can be prevented by storing the crystals under vacuum conditions. These visible crystal defects can become the nucleus for thermal decomposition.

3.12.3 Raman Spectra of AP

A Raman study of AP was conducted within the temperature range 300 to 17 K to determine the effects of low temperature on the rotational behavior of the ammonium ion, to search for evidence of hydrogen bonding, and to determine whether low-temperature phase transitions exist between 300 and 120 K [233]. The observed Raman frequencies, relative intensities, and scattering assignments are summarized in Table 8.

In the Raman spectrum (at room temperature), three components of ν_4^- , two of ν_3^- , one of ν_2^- , and one of ν_1^- were detected. No bands attributable to ν_3^+ or ν_4^+ could be detected. Upon cooling, a third component of ν_3^- , ν_1^+ , ν_4^+ , and weak components of ν_3^+ were detected. No appreciable frequency shift occurred for any band in the temperature range 300–130 K. Raman spectra revealed that no phase change occurs in AP from 300 to 120 K.

The Raman spectra of oriented single crystals of AP were measured as a function of temperature between 12 and 300 K [241]. The results were consistent with the assignment of NH_4ClO_4 crystal structure to the $D2h$ space group at all temperatures. A weak B1g mode at 180 cm^{-1} was assigned to an NH_4^+ libration. An anomalous temperature dependence was observed for low frequency B1g and B3g lattice modes, which needed further investigation in the range of 18–80 K.

Table 8: Observed Raman frequencies, relative intensities, and scattering assignments of NH_4ClO_4 at room temperature and at 130 K.

Wavenumber, cm^{-1}	Relative intensity	Wavenumber, cm^{-1}	Relative intensity	Assignment
300 K		130 K		
—	—	3320 ^a	3}	$\nu_3^{+?}$
—	—	3220 ^a	3}	$\nu_3^{+?}$
—	—	3201	13	ν_1^{+}
1417	3	1417	3	ν_4^{+}
1137	5	1137	5	ν_3^{-}
1108	10	1108	8	ν_3^{-}
1064	4	1065	10	ν_3^{-}
935	100	936	100	ν_1^{-}
921	18	922	29	$2\nu_2^{-}$
635	33	638	29	ν_4^{-}
630	36	630	16	ν_4^{-}
625	61	624	52	ν_4^{-}
461	70	462	90	ν_2^{-}

^aA series of weak overlapping bands were found in this region. Resolution and interpretation are difficult.

Data source: [233].

The NH_4^{+} ion has four fundamentals in AP at 3350 cm^{-1} (T_2 stretch), 3209 cm^{-1} (A_1 stretch), 1680 cm^{-1} (T_2 bend), and 1420 cm^{-1} (E bend) [242]. All modes become A' or A'' in the Cs sites of NH_4^{+} and ClO_4^{-} . All bands except the A_1 mode are weak and not all have been reported before in the Raman spectra. The A_1 mode was found to broaden slightly with increasing temperature. At 513 K, which is the phase transition temperature, a 10 cm^{-1} decrease in the frequency was noted along with a further increase in the bandwidth. The barrier to rotation of the NH_4^{+} ion in AP was small ($<4\text{ kJ/mol} = <1\text{ kcal/mol}$).

A detailed temperature-dependent study has been conducted to assess the Raman spectra of oriented AP single crystals in the spectral regions of lattice modes and internal vibrations of the ClO_4^{-} and NH_4^{+} ions between 10 and 300 K. This revealed that the internal modes of the ClO_4^{-} ions were splitting into several components due to site and correlation field effects [243]. The line width, frequency shift, and intensities of some of the internal modes of the ClO_4^{-} and NH_4^{+} ions and the frequency shift of a few lattice modes revealed anomalous temperature dependence around 180 and at 40 K. These anomalies have been explained in terms of phase transformations associated with the changes in hydrogen bonding strength and reorientational freedom of the NH_4^{+} ions in the lattice. The low-temperature transition at 40 K exhibits a sharp and discontinuous anomaly in some of the spectral parameters measured in this study. This is associated with order-disorder-type transition. The measured line width of the ν_1' mode in the diagonal scattering configuration can be understood in

terms of vibrational dephasing of the ν_1 excited state due to vibrational-librational coupling. The estimated activation energies in the 50–160 K and 10–40 K temperature ranges are found to be 141 and 51 cm^{-1} , respectively, which correspond to the observed NH_4^+ librational frequencies.

Single-crystal and powder neutron diffraction, coherent neutron inelastic scattering, and Raman spectroscopy have been used to study the low-temperature structure and dynamics of AP [106]. No evidence of a low-temperature phase transition between room temperature and 20 K was found. Based on analysis of thermal motion amplitudes and inelastic neutron-scattering data for ND_4ClO_4 , a Raman-active B_{3g} symmetry zone-center mode at 45 cm^{-1} was identified as a libration. Another Raman-active mode, which was a B_{1g} symmetry at 33 cm^{-1} , and a previously unobserved A_u symmetry mode at 12 cm^{-1} , were inferred to have significant librational character at $q = 0$. Comparison of these results with earlier incoherent neutron scattering results suggested that, because of the low activation energy of ammonium ions, classical jump reorientations strongly influence ammonium-ion sublattice dynamics, even at temperatures as low as 20 K.

A detailed temperature-dependent Raman spectra study of oriented single crystals of NH_4ClO_4 and ND_4ClO_4 in the lattice-mode region from 10 to 300 K allowed an assignment of the Raman bands in the lattice-mode region. This provided deeper insight into the dynamics of ammonium ions in the lattice [244]. Based on the deuterium isotope shift, characteristic changes in bandwidth with temperature, structural information, and temperature-dependent sidebands of $\pm 19 \text{ cm}^{-1}$ (10 K) from the main bands were observed. This is believed to be associated with some of the internal and lattice modes of the NH_4^+ ion below 30 K. These spectral features have been explained in terms of a model in which the NH_4^+ ion rotates almost freely around one of the axes coinciding with the $\text{N}-\text{H}(2)\cdots\text{O}(1)$ bond while it performs librational motions around the two perpendicular axes below 30 K.

The breakdown of the crystal lattice of AP in the 300–625 K range has been followed in real time by laser Raman spectroscopy [245, 246]. Examination of the external and internal modes of the ions revealed that the onset of essentially unhindered tumbling of the ClO_4^- ion seems to be intimately tied to the beginning of decomposition of AP. The effect of K^+ as an isomorphous dopant in the crystal lattice is to permit the ClO_4^- ion to tumble at a lower temperature (0.8% K^+ produces a 60–70 K lowering in the tumbling temperature) and thus decompose at a lower temperature also. All vibrational modes found in AP, including several not previously reported modes, were assigned.

3.12.4 Refractive Index of AP

The indices of refraction in the direction of the three crystal axes a , b , and c , at the wavelength of the sodium D-lines (589 nm) were measured and found to be $n_a = 1.482$, $n_b = 1.487$ and $n_c = 1.483$ [191]. Older sources have reported these as $n_\alpha = 1.4818$, $n_\beta = 1.4833$, and $n_\gamma = 1.4881$ at 589 nm.

3.13 XPS Photoelectron Spectra of Ammonium Perchlorate

XPS was used to identify the first intermediate species produced during AP initiation by varying stimuli and increasing the intensity of stimuli also [247]. Comparing species on the surface of AP damaged below the initiation threshold with that of clean AP allowed the investigators to propose an initiation mechanism. Control XPS spectra were recorded on the surface of freshly cleaved AP single crystals.

The line widths of X-ray photoelectron spectra have been found to correlate with dislocation densities in a shock-damaged crystal of AP [248]. A centimeter-sized AP crystal was loaded at several sites with a diamond pyramid (Vickers) indenter creating localized strain centers. The crystal was non-uniformly damaged by a rapidly decaying shock (peak pressure of 24.4 kbar at the entry surface), was recovered intact, and then cleaved through the indentations. The cleaved planes permitted interior analysis of the crystal by XPS over a pattern of 1 mm by 1 mm areas. The linewidth of the CL ($2p^{3/2}$) spectra ranged from 1.70 eV for the region of greatest visible damage to 1.22 eV for the region with no visible damage. This is the same linewidth as that obtained for unshocked AP (control). An approximate correlation of dislocation density versus XPS linewidth was obtained. The correlation was refined by chemically etching and determining densities on another cleaved plane in the recovered crystal.

4 Chemical Properties of Ammonium Perchlorate

4.1 Reactions with Ammonium Perchlorate

Reactions of perchlorates in general and AP in particular can be subdivided by the medium in which they occur. For rocket propellants, we are mostly interested in reactions of AP with oxidizable substances in a dry state. For the synthesis, purification, environmental fate, and disposal of perchlorates, we are mostly interested in reactions that take place in aqueous solutions. There are several books on the chemistry of perchlorates which give a good introduction into this subject area of chemistry, including [249].

The persistence of perchlorates in the environment once it has been spilled into soil and leached into groundwater is due to the lack of reactivity of perchlorate ions. Perchlorates are so unreactive in aqueous solutions that they often are used as supporting electrolytes in batteries and electrochemical cells. The conditions under which perchlorate becomes reduced in an electrochemical cell or in the presence of strong reductants depend on the galvanic potential and the pH [250].

4.1.1 Reactions of AP with Inorganic Compounds

4.1.1.1 AP Reactions in the Solid State

One of the effects that takes place during the decomposition of AP is the reaction of AP (also known as perchloric acid or perchlorate ion) with ammonia. This reaction has been investigated very thoroughly with the finding that the presence of an excess of ammonia has a distinct effect on the rate of decomposition of pure AP in that it slows it down and inhibits it significantly.

A study of the inhibiting effect of ammonia gas on the kinetics of the thermal decomposition of AP in the temperature range 488–543 K (215–270 °C) revealed that an initial ammonia pressure of about 200 mm Hg will cause full suppression of the decomposition of the orthorhombic crystals at temperatures close to the point of AP polymorphic transformation (513 K = 240 °C) [251, 252]. With the cubic crystals, only 0.5 mm Hg is the corresponding pressure required to achieve full suppression. In the case of complete inhibition of the decomposition in the presence of ammonia, AP crystals become yellowish. The activation energy of decomposition of the orthorhombic modification is 121.3 kJ/mol (29 ± 0.6 kcal/mol) in the absence of ammonia, and 159 kJ/mol (38 ± 1.1 kcal/mol) under ammonia pressure of 6.5 mm Hg. A kinetic analysis of the traditional proton transfer model of AP decomposition revealed that the increase of the activation energy in the presence of ammonia can be explained by this model.

4.1.1.2 AP Reactions in Aqueous Solutions

AP reactions in aqueous solutions are common to all perchlorate salts due to the salts usually being completely dissociated and because the ions are solvated.

While there are many methods that will remove perchlorates from contaminated groundwater there are only a few methods that will effectively destroy them. If regenerable ion exchange resins are used for water treatment the brine obtained during resin regeneration has to be disposed of somewhere. The brine was previously routinely dumped into the ocean, however, there are now restrictions with regards to doing that. Other than bioreduction, inorganic reductants were sought to reduce perchlorates to an innocuous form of chloride which can be safely dumped in surface streams or oceans.

One of the few inorganic reductants capable of reducing ClO_4^- to Cl^- is titanium(III). It is difficult to explain why weak reductants [Ti(III)] reduce perchlorates while strong reductants [Sn(II), Cr(II)] do not. The cause may be that perchlorates have to be complexed in a perchlorato complex where bridged electron transfer (an inner-sphere mechanism) can take place. The highly symmetrical perchlorate ion is a poor electron acceptor that is reluctant to give up oxygen to form chlorate. In complexes forming in ethanolic Ti(III) solutions, the symmetry of the ClO_4^- ion is distorted and it becomes more susceptible to reduction [253]. While this process may be cost-prohibitive as a method for perchlorate destruction, it may point the way to other more economical methods where the Ti^{4+} is electrically reduced back to Ti^{3+} in an electrolytic cell.

4.1.1.3 Reactions of AP with Metals

The reactions of AP with metals are very important for several reasons. While AP is being manufactured it comes into contact with many metals and may leach contaminants out of the process equipment that later adversely affect the thermal stability and the burning rate of the product. Solid propellants have to be mixed in metal containers and with metal stirrers where additional AP/metal contact may take place. Interactions between AP and the metals might cause unexpected reactions and accidental ignitions.

Reactions of Solid AP with Metals

Many AP-based composite propellants have added metal powders to increase the heat of combustion of the propellant and reduce its propensity for chamber pressure oscillations. Premature reactions between AP and the metals (mostly aluminum) might cause unwanted ignitions or limit the storage shelf life of the propellants. In some instances the AP and the metal powder are mixed together before the binder is added. The dry mix is a potentially hazardous operation, which is why the hazard properties of dry AP/metal mixtures have been extensively tested.

The effects of aluminum and nickel powders of various grain sizes on the thermal decomposition of AP were investigated by TGA and DSC in a dynamic nitrogen atmosphere [254]. The TGA results demonstrated that Al powders have no effect on the thermal decomposition of AP which are conventional grain sizes, while the nanometer-sized Ni powders have a great influence on the thermal decomposition of AP with conventional or superfine grain sizes. The results obtained by DSC and *in-situ* FTIR analysis of the solid residues confirmed the catalytic effects of nano-nickel. The burning-rate enhancing activity of nano-nickel may be caused by acceleration of the gas phase reactions during the second step of AP decomposition.

AP mixed with varying amounts of aluminum powder (or any combustible metal) is a powerful and sensitive explosive. AP mixed with aluminum powder ("aluminized AP") or wax is also a powerful explosive [255]. When mixing propellants containing AP and aluminum, one will not want to dry-mix the two ingredients before adding the binder unless taking special precautions.

The onset of thermal decomposition of AP lowers in the presence of ferrosilicon containing 20–25% Fe [256]. Ferrosilicon in an AP:FeSi ratio of 10:3 and serves both as a catalyst and performance enhancer. It is also useful for propellants in which part of the AP has been replaced with NaNO_3 as a chloride scavenger to avoid the formation of HCl in the exhaust.

Reactions of AP Solutions With Metals

Perchlorate ion in a solution is relatively difficult to reduce. Reduction reactions have been studied as a means of perchlorate removal from polluted drinking water (see Section 8.9.10). The reduction of perchlorate ion with iron metal with illumination using UV light has been tested as a method for removing perchlorates from contaminated

groundwater to restore its quality as drinking water [257]. While the reaction of perchlorates using iron in the dark is very slow, it can be accelerated by using UV light of sufficiently short wavelength ($<185\text{ nm}$). The metallic iron provides electrons for the reduction of perchlorates all the way to chloride, while less than 1% stays behind as chlorate. Chlorate is an intermediate in the reduction process. Bacteria will also digest perchlorates and iron(0).

The kinetics of perchlorate reduction using elemental iron has been examined at elevated temperatures using microwave heating and conventional heating [258]. Results from microwave heating study revealed that 98% of aqueous perchlorates can be removed in one hour at 473 K (200 °C). The rapid and complete reduction of perchlorates using elemental iron at elevated temperatures suggests that iron reduction processes at elevated temperature and pressure may be an option for complete removal of perchlorates from polluted water and industrial discharges.

Large quantities of AP/binder/Al propellant have to be removed from outdated rocket motors or as part of demilitarization efforts. One of the safest methods of demilitarization is the removal of propellant from motors using a high-pressure water lance. Slow reactions between dissolved AP and suspended Al may take place while the leached oxidizer and the particulates are waiting to be separated for further processing (and eventual recycling of the AP).

4.1.1.4 Reactions of AP Solutions With Metal Hydrides

Since the majority of composite propellants contain AP, it may react unexpectedly with a variety of solid propellant ingredients. The specific impulse of solid propellants can be improved by addition of metals and/or metal hydrides. One of the metal hydrides with the best I_{sp} improvement is beryllium hydride. Studies of the decomposition of AP revealed the first step to be the dissociation into gaseous ammonia and anhydrous perchloric acid. The subsequent reactions are the combustion of the various hydrogen species, including metal hydrides with perchlorate species. The hydrogen atoms, oxygen atoms, and chlorine atoms also recombine to H_2 , O_2 , and Cl_2 by three-body collisions. The reaction between beryllium hydride and AP produces BeO but does not produce BeCl or $BeCl_2$ [259].

4.1.2 Reactions of AP With Organic Compounds

The primary interest in the reactions of AP with organic compounds is the potential reaction of AP with binders during mixing, curing, storage, and actual burning. AP/binder reactions underneath the flame front determine the temperature of ignition and the burning rates. Reactions with polymeric binders are discussed in Section 4.1.2.4. Because it is sometimes difficult and messy to mix AP with actual binders in small batches, other more easily obtained organic compounds have often been substituted for polymeric binders in laboratory tests of AP combustion. Experimental methods to study reactions of AP with organic compounds (polymeric

or not) include DTA, DSC, TGA, ARC, sandwich burners, T-jump FTIR, T-jump mass spectrometry, Raman spectroscopy, and mass spectrometry.

In an effort to identify where the AP decomposition products attack the weak links in an organic molecule the reactions of AP with aromatic compounds substituted with amino, methyl, and carboxyl groups were studied by measuring the burning rates of pressed pellets in a combustion bomb under nitrogen pressure [260]. The introduction of amino or methyl groups into the benzene ring increased the burning rates in proportion to the number of groups introduced. Such studies can help in developing formulations with higher burning rates. On the other hand, if one avoids amino groups, the propellant can have better thermal stability.

The effects of 5% urea, oxamide, dicyandiamide, poly(vinyl chloride), hexachloroethane, diphenylamine, urethane, anthracene, hexamethylenetetramine, salicylic acid and its derivatives (benzoic acid and its derivatives), and 8-hydroxyquinoline on AP combustion characteristics at pressures up to 10.13 MPa (100 atm) were investigated [261]. The lower pressure limit of stable combustion, combustion rate, and coefficients of inhibition in the exponential equation of combustion (dependence of burning rate on pressure) have been determined. The chemical structure of the additive was related to the combustion characteristics of AP. The effect of the additives on the primary dissociation of NH_4ClO_4 and on the decomposition of HClO_3 was discussed in detail. Reaction of poly(methyl methacrylate) tubes used for sample containment can change the combustion rate at most pressures. The results were compared with the results for similar systems containing RDX instead of AP.

The combustion of AP-based composite propellants has been studied at pressures between 100 kPa and 20.6 MPa (15 and 3000 psi) in order to determine the mechanisms by which the fuel components influence the burning rate of the composites [262–265]. To have flexibility in the choice and concentration of the fuel components, all combustion experiments were performed with pressed powder strands. The fuels studied included those which were expected to affect the combustion mechanism of the composite primarily through their effect on: (1) the oxidizer decomposition mechanism and (2) the composite surface temperature. The combustion of pure and doped AP was studied using both pressed powder strands and pressed end-burning motor grains. The objective was to study the reactions which occur on or immediately adjacent to the surface (“zone of influence”) of burning composite propellants. The fuels included benzoic acid, hydroquinone, isophthalonitrile, triphenylmethane, aluminum, phenolic resins, sucrose, benzamide, acetamide (fuels producing ammonia), succinamide, phthalamide, and phthalamic acid. A composite with a relatively unreactive fuel such as benzoic acid had a lower burning rate than a similar composite with a more reactive aliphatic acid such as stearic acid. At pressures above 6.88 MPa (~1000 psi) the burning rate of the benzoic acid composite was lower than that of pure AP. Composites with fuels which char on decomposition have higher burning rates than composites with similar fuels which volatilize without charring. This has been demonstrated both for a series of fuels in which char occurs due to dehydration and in a series of fuels

where char forms due to dehydrogenation. Fuels (amides, diamides, and acid amides) which decompose thermally at temperatures below the composite surface temperature to form NH_3 or H_2O significantly affect the combustion rate of AP composites at all pressures. Generally, these fuels lower both the burning rate and the burning rate pressure exponent. There are ions which have both the thermodynamic potential and the kinetic reactivity to reduce perchlorate ions in a solid-solid or solid-liquid reaction. Ions such as CNO^- , CN^- , and SCN^- all react with KClO_4 in a DTA to cause deflagration and detonation. Composites containing fuels with functional groups (e.g., nitriles) which have the potential to reduce perchlorate ions generally have relatively large burning rate pressure exponents above 13.76 MPa (~2000 psi).

Urotropine was mixed with AP, then pressed to pellets and burned in a strand burner at varying pellet compression densities, different pellet confinement, and two different chamber pressures [266]. The main objective of the study was to measure the effect of density on the burning rate of pure AP pellets. The urotropine was added only for comparison.

4.1.2.1 Reactions With Nitrate Esters

The unwanted reaction of AP with nitrate esters in composite modified double-base propellants can be retarded with the addition of a stabilizer, resorcinol, which is applied via co-crystallization. This occurs by first dissolving AP in liquid ammonia then adding 1–10 mass-% resorcinol [267]. The solution is evaporated at room temperature following which the crystals are dried at 311–339 K (100–150 °F) for 0.5–1 hours. They are then held in 25 mm Hg vacuums at room temperature for 72 hours.

4.1.2.2 Reactions With Nitramines

Based on the condensed-phase mechanism and thermolysis experimental results, synergistic interactions between AP and HMX in nitrate ester plasticized polyether (NEPE) propellants were studied from the two viewpoints of molecular structure and chemical reaction [268]. Related to bond polarity, formal charges, chain reaction theory, and the systematic comparison of solid monopropellant combustion and modeling, a [linkage-mutualism] mechanism was proposed. AP content and particle size can influence the mechanism. Therefore, they will have significant effects on the ignition and combustion characteristics of AP/NEPE propellants.

4.1.2.3 Reactions With Other Organic Matter

Perchloric acid is sometimes used to destroy organic matter in environmental, biological, petrochemical, and geological samples and to prepare them for the analysis of trace metals by fuming the sample in a crucible under the fume hood (“wet ashing”). This is one of the pathways through which unwanted perchlorate ions find their way into waste streams. Changing the fuming procedure has been proposed so as to capture and trap the perchloric acid fumes instead of allowing them to go up the fume stack [269]. Hot, boiling perchloric acid for this application has to be at least 50%

HClO_4 . The CRC Handbook of Laboratory Safety [270] reports several accidents caused by perchlorate deposits in improperly constructed fume hood systems.

4.1.2.4 Reactions of AP With Organic Polymers

Reactions of AP with organic polymers can potentially occur prematurely during mixing, curing, or storage stages and will definitely occur if burning a solid propellant grain.

PS is not a preferred binder for solid propellants. Nonetheless, it is sometimes used for fundamental studies in laboratories in academic settings because it is readily available. The kinetics of the decomposition of catalyzed AP with and without the presence of PS has been measured over a wide temperature range [271, 272].

A clean-burning polymer that is easily processed and is available as a powder with a wide range of molecular weight and particle sizes is polyethylene (PE). Consequently, it has been used as a model binder instead of the more difficult to cure carboxy-terminated polybutadiene (CTPB) or HTPB binders. AP can be mixed with PE powders and additives and pressed to pellets for subsequent burning rate studies. Another clean burning binder is NEPE. The thermal stability of perchlorate composite propellants was studied at 408 and 443 K (135 and 170 °C) [273]. The objective was to determine the importance of heterogeneous oxidizer-fuel reactions in thermal degradation processes. The experimental approach used to elucidate the mechanisms by which the oxidizer/fuel composites thermally degrade was divided into two parts: (1) keeping the fuel type the same and varying the nature of the oxidizers, and (2) holding the oxidizer constant and varying the fuel components. The fuel component primarily utilized was PE. Oxidizers included KClO_4 , KClO_3 , NH_4ClO_4 , and NH_4ClO_4 doped with chlorate, phosphate or arsenate. In the second phase, the oxidizer used was primarily NH_4ClO_4 while the fuels included saturated and unsaturated polybutadiene prepolymers and a series of bonding agents.

There are many reports on the thermal stability of AP in contact with various polymeric binders such as those used in composite propellants. However, quite often the oxidizer particles are not in direct contact with the binder; they are coated first with a bonding agent. The effect of the bonding agent on aging of composite propellants must also be considered.

Delamination of oxidizer particles can lead to increased burning rates and a loss of mechanical strength. SEM was used to examine the failure sites in thermally degraded AP composite propellant samples [274]. The formulation variables tested were oxidizer purity, oxidizer particle size, and oxidizer to binder bonding agent. The binder, a saturated hydrocarbon, was kept constant throughout the experiments. The oxidizers were: AP, chlorate-doped AP, arsenate-doped AP, and phosphate-doped AP. The oxidizer bimodal particle size distribution was 60% of the large fraction and 40% of the small fraction. The bonding agent, when present, was used at the 0.15% level. The data revealed that both the oxidizer purity and particle size had a strong effect on the thermal degradation process. The effect of the oxidizer particle size was more notice-

able at higher temperatures and stress levels. An examination of the failure sites using SEM of propellants subject to higher temperatures and stress conditions indicated that the fracturing of large oxidizer particles led to propellant cracking.

Kinetic studies revealed that in binders involving epoxy resins and carboxyl groups in polybutadiene-acrylic acid-acrylonitrile terpolymers, the rate of the polymerization reaction is reduced and the epoxy groups are consumed faster than carboxyl groups in the presence of AP. Various coatings were evaluated to prevent or retard the oxidizer-epoxide interaction. The coatings, which can be adsorbed from solution on AP, were deposited on a fluidized bed of the oxidizer or were merely added to the propellant formulation, as described in Section 2.1.8. Since consumption of epoxy groups in AP-epoxy resin mixtures have been shown to be independent of the amounts of AP present, it was concluded that this interaction was related to the solubility of AP in the binder system. The solubility of AP in Epon[®] H-825 was determined. Methods of chemically capturing AP or its ionization or decomposition products as they appear in solution were investigated. K, Rb, and Cs salts, which form perchlorates of very low solubility in organic systems, were effective in reducing the AP-epoxy interaction and precipitating perchlorates from solutions in organic binders [80]. Similar oxidizer-epoxy interactions prevented the curing of polybutadiene acrylonitrile (PBAN) propellants with hydroxylammonium perchlorate. Attempts were made to coat it with toluene diisocyanate (see [275] also).

4.1.3 Electrochemical Reactions of Perchlorates

Perchlorates are produced via the electrochemical oxidation of chlorates. It should be possible to reverse this reaction in an electrolysis cell and reduce perchlorates to chlorate or even lower states of oxidation of chlorine.

The electrochemical reduction of perchlorates is mostly of interest for the decontamination of polluted drinking water (see Section 8.9.7).

The reduction of ClO_4^- ions in acid media was studied at smooth polycrystalline rhodium electrodes using voltammetry, chronoamperometry, and impedance spectroscopy [276]. Based on experimental results, a new mechanism for the electrocatalytic reduction of ClO_4^- ions has been proposed. This is based on the assumption that the reduction process starts with the adsorption of perchlorate ions at free active sites on a metal surface. It was also assumed that the whole process occurs on the surface and the role of desorption of intermediates can be neglected.

4.2 Analysis of Ammonium Perchlorate

Analytical methods are required for quality control of AP and for the detection of traces of AP in the environment. The persistence of perchlorate ions in aquifers made the development of sensitive analysis methods for perchlorate a very high priority item

during the 1990s. A review of various analytical methods for perchlorate analysis in a variety of matrices has been provided within [277]. This publication also compares different methods for specificity, sensitivity, and reliability.

The following chapters on the analysis of perchlorates can be subdivided by the matrix in which perchlorates are to be analyzed or by the methods used (see [278]).

4.2.1 Quality Control of AP

AP from different vendors may meet all military specification (MIL-SPEC) requirements but still produce different burning rate results when formulated into a composite propellant.

4.2.1.1 Assay of AP

Previously, a procedure set forth in the Military Specification JAS-A-192 specified the reduction of perchlorate to chloride via fusion in a Parr bomb and the subsequent determination of chloride by an argentometric titration. These procedures were time-consuming and subject to errors due to incomplete reduction and the inevitable spattering of the sample.

A more direct method is the reduction of perchlorate ion with a 15 mol % excess of titanium(III) chloride in strongly acidic and boiling hot solutions according to [279, 280]:

The boiling time is 15 minutes but can be reduced to eight minutes if a trace of osmium(VIII) (which acts as a redox catalyst) is added to the solution. The excess Ti(III) is then back titrated with standard ferric ammonium sulfate solution:

using thiocyanate as the indicator.

A round robin exercise was conducted for the purpose of evaluating three assay methods for AP [281]. Eleven government and commercial laboratories submitted quadruplicate analyses for two different samples. These results were subjected to statistical analysis-of-variance to estimate the significance of interlaboratory variation. It was found that the laboratories were unable to reach an agreement, regardless of the methods used.

A comparison of AP assay using the distillation method and the formaldehyde method found that the difference between the two methods can amount to 0.35 to 0.22% [282].

4.2.1.2 Water Content of AP

One of the most common contaminants in AP which has been around for a while is water. The hygroscopicity of AP is not as bad as that of AN [283] Although AP is not very

hygroscopic (and not nearly as bad as AN or ADN), moisture absorption is a serious problem to contend against. Excessive moisture in the presence of isocyanate curing agents could result in bubble formation due to evolved CO_2 . It can also cause irregular mechanical and burning behavior of the cured propellant. This is problematic as moisture in AP affects the nucleation and onset of thermal decomposition.

Water in AP can be determined by a Karl-Fisher titration. The determination of water in AP by Karl Fischer titration is simple and straightforward and it is also accurate. However, the use of automatic titration equipment in this determination has resulted in wide divergence of results [284, 285]. Depending on the operating method used, one can selectively measure the surface water on the particles or the total water of dissolved crystals. The accurate titration of small water contents of AP requires that the commercially available and stabilized Karl Fischer reagent first be diluted so the amount of reagent consumed can be measured more accurately with the 10-mL burette generally employed with the autotitrator. The time required for a complete titration can be considerably reduced in the presence of dissolved salts and by using a 3:1 pyridine-methanol solution as the titration medium. Two samples of AP, one with 0.01 and the other with 0.05% H_2O , were sent to eight laboratories for a round-robin analysis. The improved method was shared with all eight laboratories and the results of the round-robin effort was compared and statistically evaluated. An analysis method using the METTLER Karl-Fischer DL-38 automatic moisture analyzer to determine the water content of UFAP was simple and rapid, and had good repeatability and a small deviation [286].

4.2.1.3 Contaminants in AP

The production of AP using the metathetical reaction of sodium perchlorate and ammonium chloride, with the sodium perchlorate having been prepared via the oxidation of sodium chlorate, leaves detectable amounts of chlorate ion in the product. It is an absolute [VERBOTEN] among propellant and pyrotechnics formulators to have chlorates and ammonium salts in the same composition. Ammonium chlorate, NH_4ClO_3 , even in small quantities, is very unstable [287] and would cause any formulation containing AP and chlorate ion to have reduced thermal stability. The chlorate contaminant concentration in AP can be determined spectrophotometrically, either by using the reaction with brucine [288] or benzidine [289, 290] or by tracing the change of pH as indicated by methyl orange during the reaction of chlorate or bromate with chloride in acidic media [291].

The lattice parameters of six samples of AP and AP/KClO_4 solid solutions were determined by wide angle XRD using fixed count techniques [292]. The results indicated that this technique could be used to monitor the purity of AP with regard to KClO_4 as solute in the AP/KClO_4 solid solution system.

In AP production, chlorate impurities in the raw material will influence the thermostability of the produced AP and any propellants formulated therewith. Four different methods for eliminating chlorate contamination in AP were evaluated [293].

It was discovered that the $\text{HCl} + \text{H}_2\text{O}_2$ process works best. That involves reacting the $\text{V}(\text{NaClO}_4) : \text{V}(\text{HCl}) : \text{V}(\text{H}_2\text{O}_2) = 400 : 4 : 1$ mixture for one to one-and-a-half hours at 363 K (90 °C), and continuing the reaction 15 to 30 minutes after stopping the heating process. This treatment reduces sodium chlorate impurities in the sodium perchlorate solution from which AP is made by metathetical substitution to below 0.014%, which is the maximum allowed per the Chinese national military specification.

4.2.2 AP Military Specifications

AP Military Specifications have evolved over time, reflecting the improvement in manufacturing techniques and the tighter quality control for solid propellants in a wide array of military applications (Table 9).

As of 1963, one of the applicable AP specifications has been MIL-A-192A, Amendment 2, which described two grades on the basis of moisture content plus a modification which contains the conditioning agent TCP. Each grade may have seven classes of particle size distribution. Despite the seemingly large number of grades and classes, propellant manufactures have found this specification to be inadequate for their needs and company specifications, or their purchase descriptions were used instead. Standardization is completely lacking and this undoubtedly contributed to confusion and increased costs. Another revision of MIL-A-192A was made in an attempt to overcome this situation [294]. It did not accomplish its purpose, however. This was mainly because it failed to include certain details regarding newer tests and requirements. In addition to this, the specification was inadequate with regard to the particle size requirements. The latter was difficult to specify because the particle size distribution required for optimal performance was still in flux.

4.2.3 Emission Spectrographic Methods

Emission spectrographic methods can be used for analysis of metallic contaminants in AP and other ammonium salts. Inductively coupled plasma-atomic emission spectrography can be used for simultaneous multi-element determinations of various suspect metals in AP.

One of the methods of working with solid samples that is widely used for the identification of small samples of energetic materials (which is often a task in forensic investigations) is nanosecond Laser Induced Breakdown Spectroscopy (LIBS). LIBS is a new technique used for the detection and identification of very small samples of chemical, biological, explosive, and hazardous materials. LIBS vaporizes a target with an intense laser pulse, which generates a very hot plasma. The spectral emission from the plasma contains a specific signature of atoms relating to the material, including nitrogen and oxygen.

Laser-induced breakdown spectroscopy analysis of AN and AP revealed characteristic lines corresponding to O, N, H, C, and K [295]. The oxygen line at 777.38 nm and three nitrogen lines (N1, N2, N3) at 742.54, 744.64, and 747.12 nm were used for evalu-

Table 9: Military specifications for AP.

ating the O/N atomic ratios. The intensities were calculated using the area under the peaks and were normalized to their respective transition probabilities and statistical weights. The O/N ratios estimated from the LIBS spectra were ~4.94 and ~5.11 for AP and ~1.64 and ~1.47 for AN, which is quite different from the actual stoichiometric ratios (four for AP and one for AN).

4.2.4 Quantitative Analysis of AP in Environmental Samples

The quantitative analysis of perchlorate ion in environmental samples (soil, water, fertilizer, vegetation) must be done very accurately because the results may have legal implications if a polluted site near an industrial source of contamination is examined. There are numerous potential interferences that need to be considered. An excellent survey of analytical methods for perchlorate is provided by Urbansky [296].

A chapter in the book *Perchlorate: Environmental Problems and Solutions* by Sellers et al., [297] contains a section on analytical methods. This provides an excellent summary of sample preparation and analytical methods available.

While a rapid degradation of perchlorates in aquifers and polluted waters would be desirable, degradation of perchlorate in water samples during transit from the sampling site to the analytical laboratory may alter the results depending on how long the sample has been sitting around before it was analyzed. The determination of perchlorate cannot normally be carried out in the field. Water samples for perchlorate analysis are often shipped to a central laboratory where they may be stored for a significant (this is variable and depends on the workload) period before analysis. The effect of such storage was not known until the long-term stability of perchlorate ion in deionized water, tap water, groundwater, and surface water was actually examined under carefully controlled conditions [298]. Sample sets containing 1000, 100, 1.0, and 0.5 µg/L perchlorate ion in deionized water and also in local tap water were formulated. These samples were analyzed using ion chromatography for perchlorate ion concentrations against freshly prepared standards every 24 hours for the first seven days, biweekly for the next four weeks, and periodically after that for a total of 400 or 610 days for the two lowest concentrations and a total of 428 or 638 days for high concentrations. All samples except for the surface water samples were found to be stable for the duration of the study, allowing for holding times of at least 300 days for groundwater samples and at least 90 days for surface water samples.

4.2.4.1 Gravimetric Methods

Most perchlorates are very soluble in water and there are only very few insoluble perchlorates.

Gravimetric methods for analysis of perchlorates are used mostly for the assay of samples with high perchlorate content (AP, composite propellants). Reagents that can precipitate perchlorate are nitron (3,5,6-triphenyl-2,3,5,6-tetraazabicyclo-[2.1.1]hex-1-ene; 1,4-diphenyl-3-phenylamino-1,2,4-triazolium hydroxide inner salt; 4,5-dihydro-2,4-diphenyl-5-(phenylimino)-1H-1,2,4-triazolium hydroxide inner salt), tetraphenylarsonium chloride [299], or 2,4,6-triphenylpyrylium chloride [300].

Nitron precipitation suffers from many interferences because all large ions (bromate, iodide, nitrate) are also precipitated.

4.2.4.2 Detection of AP in Water

Before 1997, perchlorate could not be readily detected in groundwater at concentrations below 100 µg/L, until the California Department of Health Services developed an acceptable analytical method that lowered the detection limit to 4 µg/L. Subsequently, groundwater samples containing perchlorate were soon encountered in several western states and gross contamination became apparent in the Colorado River. The discovery of perchlorate in the aquifers feeding municipal drinking water sources has resulted in extensive investigations about the source of the contamination, the rate of its dispersal, and the possible consequences of perchlorate ingestion (if consumed with drinking water). All these studies depend on the availability of a reliable method of analysis for perchlorate ion in water.

Because perchlorate ion in water is not very reactive there are not many reagents that can be used for the determination and identification of AP in water. Water contamination studies over the past two decades have proposed methods for analysis of perchlorate in water, thus allowing this area to improve substantially.

The EPA has issued three recommended analytical methods for the analysis of perchlorate in drinking water:

EPA, Method 314.1, Determination of perchlorate in drinking water using inline column concentration/matrix elimination ion chromatography with suppressed conductivity detection. US Environmental Protection Agency, Office of Ground Water and Drinking Water. EPA815R05009 (2005)

EPA, Method 331.0, Determination of perchlorate in drinking water by liquid chromatography electrospray ionization mass spectrometry. US Environmental Protection Agency, Office of Ground Water and Drinking Water. EPA815R05007 (2005)

EPA, Method 332.0, Determination of perchlorate in drinking water by ion chromatography with suppressed conductivity and electrospray ionization mass spectrometry. US Environmental Protection Agency, Office of Research and Development. EPA600R05049 (2005)

A very good summary of analytical methods for perchlorates is contained in [301].

A ClO_4^- reductase-based biosensor for rapid determination of ClO_4^- in water was developed using a ClO_4^- -sensing bio-electrode made by coating *Dechlorosoma sp.* ClO_4^- reductase on a Nafion (ion-exchange matrix) layer pre-coated on the polished surface of the glassy carbon electrode [302]. The response time was $\sim 111 \pm 28$ s. A linear correlation was established between biosensor response (measured in nA) and ion-chromatography conductivity readings (measured in µS). Biosensor response to ClO_4^- was optimum at an applied potential of -0.6 to -1.0 V. ClO_4^- reduction was maximal in the pH range from 7.6 to 8.0. The ClO_4^- biosensor was stable even after repeated use (24 analyses were conducted on day one over a ten-hour period at room temperature).

A microchip capillary electrophoresis system using contact conductivity detection has been developed for the determination of perchlorates in water. This is an inexpensive and portable system for routine online monitoring of perchlorates in drinking

water [303]. The method has several advantages including reduced analysis times relative to IC, inherent portability, high selectivity, and minimal sample pre-treatment. The system is capable of detection limits of 3.4 ± 1.8 ppb ($n = 6$) in standards and 5.6 ± 1.7 ppb ($n = 6$) in drinking water.

Trace levels of perchlorate can be determined using total reflection X-ray fluorescence (TXRF) [304]. Perchlorate anions were concentrated on anion-selective membranes that had been prepared on the surface of quartz reflectors. The reflectors were immersed in water solutions containing nanogram per milliliter (ppb) concentrations of perchlorate. After this step, the reflectors were taken out of the solution and were analyzed using TXRF. Minimum detection limits lower than 1 ng/mL and good linearity at the concentration range of 1–50 ng/mL were achieved.

4.2.4.3 Electrochemical Methods

Perchlorate ions can be analyzed using ion-selective electrodes, although other ions may interfere with the process [305]. Two types of electrodes, without an inner reference solution, were constructed using octylammonium chloride as the sensor, a mixture of dibutyl phthalate and *o*-nitrophenyloctyl ether as the solvent mediators, and polyvinylchloride (PVC) as the plastic matrix. The membranes were obtained via direct application onto a conductive epoxy resin support. The limit of detection of the direct potentiometric method developed was found to be 0.01% and the precision and accuracy of the method expressed in terms of mean relative standard deviation (RSD) and average percentage of spike recovery were 0.4% and 100.5%, respectively.

4.2.4.4 Ion Chromatographic Methods

EPA method 314.1 relies on ion chromatography with conductivity detection. If a pre-concentration column is used, the detection limit can be as low as 0.14 µg/L (Table 10). But this method also requires a second analysis on a different column to verify all peak assignments and reduce the chance of false-positive reports.

Table 10: Perchlorate ion chromatographic analytical method performance.

EPA Method	Operating mode	LCMRL ^a
331.0	Direct injection (200 µL) with matrix diversion, LC-MS or LC-MS-MS detection	0.02 ppb
330.0	Direct injection (200 µL) with matrix diversion, IC-MS or IC-MS-MS detection	0.04 ppb
314.1	Preconcentration (3 mL) with matrix rinse, suppressed conductivity detection	0.1 ppb

^aLowest Concentration Method Reporting Limit (LCMRL).

There are several ion chromatographic methods for the analysis of perchlorates in solutions [306, 307]. Most of these use conductivity detection and some work even in the presence of a high degree of salinity [308].

An electrospray ionization mass spectrometry method was used to check for trace concentrations of perchlorate in drinking water samples from southern Nevada at 8–9 µg/L [309].

Perchlorates in the low µg/L range can be analyzed using ion chromatography, either with pre-concentrations [310] or without [311–316]. These methods are linear over the range of 2–100 µg/L. Quantitative perchlorate recovery was demonstrated in spiked drinking water and groundwater samples.

An ion chromatographic method that reduces the amount of interference of other total dissolved solids (TDS) ions used a silver-saturated ion exchange resin in a Dionex AS16 separation column [317]. This sample preparation method was based on the unusually high solubility of silver perchlorate. It was found that the silver perchlorate would remain in a solution while most of the other interfering anions would precipitate out at the surface of the ion exchange resin in the form of their silver salts. This way background conductivity was dramatically reduced and any excess silver would remain on the resin. The calibration curve was linear over five orders of magnitude. The MDL for perchlorate was 0.19 µg/L.

Perchlorate was generally not detected in surface water samples collected from 50 sites across the Great Lakes Basin [318]. Concentrations of only six samples were near the MDL of 0.2 µg/L.

A new method was developed for the analysis of perchlorate in water by using reversed-phase liquid chromatography/electrospray ionization-mass spectrometry/mass spectrometry (LC/ESI-MS/MS) in the negative ESI mode [319]. Selective and sensitive perchlorate detection was obtained by monitoring the $^{35}\text{ClO}_4^- \rightarrow ^{35}\text{ClO}_3^-$ and $^{37}\text{ClO}_4^- \rightarrow ^{37}\text{ClO}_3^-$ mass transitions. The $^{35}\text{ClO}_4^- \rightarrow ^{35}\text{ClO}_3^-$ transition was quantitated against the internal standard ^{18}O -labeled sodium perchlorate ($\text{NaCl}^{18}\text{O}_4$). $^{37}\text{ClO}_4^- \rightarrow ^{37}\text{ClO}_3^-$ transition was examined to provide additional specificity. The method sensitivity, accuracy, and precision were investigated by analyzing fortified blank samples, field samples, and performance evaluation samples. The results (1.01–13.5 µg/L) for the proficiency evaluation samples differed from the certified values (1.04–14.1 µg/L) by 3–18%. This new reversed-phase LC/ESI-MS/MS method is rapid, accurate, and reproducible. The calculated MDLs were 0.007 µg/L for deionized reagent water and 0.009 µg/L for synthesized reagent water, respectively. The minimum reporting limit was 0.05 µg/L.

An alternative, rapid, and reproducible method of analysis of perchlorate in food products makes use of a rugged and inexpensive C18 column, a multi-mode OASIS HLB solid-phase extraction cartridge for sample clean-up, and acetic acid for pH adjustment and protein precipitation [320]. Detectable perchlorate levels in selected commercial food samples were <1.0–2.1 ng/g (fruit and vegetable juices), <1.0–5.0 ng/g (milk), and <1.0 ng/g (bottled water).

A method for the analysis of perchlorates in human saliva samples, using a dilution and ultrafiltration technique, isotopically labeled standards (Cl^{18}O_4), and liquid chromatography-tandem mass spectrometry (LC-MS/MS) offers great selectivity and sensitivity [321]. The LC-MS/MS calibration was found to be linear over the range of 0.01 to 50 ng/mL and for 100 μL injections (i.e., 1–5000 pg injection). The method quantitation limit (LOQ) was 0.4 ng/mL, which includes a sample dilution factor. Salivary concentrations of a convenience sample of 83 persons working and/or living in Albany County, New York, ranged from 0.4 to 37 ng/mL with a mean concentration of 5.3 ng/mL. Analysis of perchlorate in saliva from a population ($n = 86$) with no major sources of exposures, using the method developed in this study, suggests the ubiquitous occurrence of perchlorate in saliva.

4.2.4.5 UV-Vis Absorption Spectroscopic Methods

A spectrophotometric method first precipitates all perchlorates with an excess of nitron then determines the unused nitron in the supernatant solution [322]. Because nitron itself has no absorption suitable for UV-Vis spectrophotometry, it is converted to a red dye ($\lambda_{\text{max}} 490 \text{ nm}$) by reaction with NaOH. The detection limit is about 100 $\mu\text{g/mL}$ within the original sample.

4.2.4.6 Raman Spectroscopic Methods

Surface-enhanced (SERS) and normal Raman spectroscopy can be used for detecting ClO_4^- at low concentrations. The use of selective sorbents greatly enhanced the reproducibility and sensitivity of ClO_4^- detection when using a normal Raman spectroscopy. It was found that ClO_4^- is SERS active and it is possible to detect ClO_4^- at concentrations initially as low as 10^{-6} – 10^{-7} M (or 10–100 $\mu\text{g/L}$) [323]. Later, measurements as low as 10^{-9} M were seen [324]. Quantitative analysis of ClO_4^- was validated with good reproducibility by using both simulated and contaminated groundwater samples. When coupled with a portable Raman spectrometer, this technique has the potential to be used as an *in-situ* rapid screening tool for perchlorates in the environment.

Raman spectroscopy can determine perchlorate loading on a non-selective ion exchange resin such as Purolite A850 acrylic gel [325]. This method was tested using laboratory water samples and actual California groundwater samples with the complexities of competing ions, dissolved organics, and other potential interfering agents. The detection limit for this method of measuring perchlorates on resin was found to be 0.014 meq/g. A linear correlation between resin loading with perchlorates and the intensity of the Raman perchlorate signal was quantitatively verified.

4.2.4.7 Mass Spectrometric Methods

Mass spectrometry is most often used after pre-separating the samples using ion chromatography but it can also be used as a method by itself. EPA methods 331.0 and 332.0 are more sensitive as well as more definitive for perchlorates than EPA method 314.1.

Both EPA methods 331.0 and 332.0 incorporate an internal standard to minimize bias from interferences or instrument variability. A known amount of perchlorate with $^{35}\text{Cl}^{18}\text{O}_4^-$, which reaches a peak at 107 atomic mass units, was added as an internal standard. In addition to monitoring amu 99, 101, and 107 in the effluents, one can also monitor daughter ions that have lost one oxygen and show up at 83, 85, and 89 amu. This technique has been called [multiple reaction monitoring] and greatly enhances the specificity of the method.

An electrospray ionization mass spectrometry/mass spectrometry (ESI/MS/MS) method was developed to measure part-per-billion ($\mu\text{g/L}$) concentrations of perchlorates in groundwater [326]. Selective and sensitive perchlorate detection was achieved by operating the mass spectrometer in a negative ionization mode and by using MS/MS to monitor the ClO_4^- to ClO_3^- transition. The method of standard additions was used to address the considerable signal suppression caused by anions that are typically present in groundwater such as bicarbonate and sulfate. ESI-MS/MS analysis was rapid, accurate, reproducible, and provided a detection limit of $0.5\mu\text{g/L}$ perchlorates in groundwater.

The electrospray mass spectrometer method was found to have a perchlorate detection limit of 0.38 ppb, whereas ion chromatographic methods in use at that time had a detection limit of only 4 ppb [327]. The minimum reporting limit was 1 ppb. The mobile phase for the analysis consisted of 0.5% acetic acid in acetonitrile. Chlorine-containing peaks were detected at m/e of 99.1 (ClO_4^-), 140.1 (the $\text{H}_3\text{CCN}\cdot\text{ClO}_4^-$ adduct), and 159.12 (the $\text{H}_3\text{CCOOH}\cdot\text{ClO}_4^-$ adduct). A linear correlation was found between the peak areas of the $m/e = 99.1$ peak and the perchlorate standard concentrations from 0.5 to 100 ppb.

Because it is a small inorganic anion, perchlorate quantitative analysis is most amenable to electrospray atomization/ionization in the inlet of a mass spectrometer. Low detection limits of the order of 5 ng/L have been demonstrated in the absence of interfering ions. However, in the presence of other chlorine-containing anions, this method is less reliable. If the perchlorate ion could be selectively paired with a host molecule that will raise its m/e by a few hundred units above the noise level of the other water-dissolved solids, the selectivity and sensitivity for perchlorate would be greatly improved. Five organic bases and a cationic surfactant were tested as complexants/extractants and the best results (limit of detection 10 ng/L) were obtained with chlorhexidine [328]. Multiple perchlorate ions can associate with a single chlorhexidine molecule.

In electrospray liquid chromatography/mass spectrometry/mass spectrometry, perchlorate is quantitated by monitoring the ion signal from mass 83, which is formed by a loss of an oxygen atom from the perchlorate molecular ion. The aqueous MDL is $0.05\mu\text{g/L}$ and was determined using an actual groundwater matrix [329]. The soil MDL is $0.5\mu\text{g/kg}$ and was determined using Ottawa sand. A stability study was performed by spiking water samples at 0.25, 10, and $20\mu\text{g/L}$ and analyzing them 50 days later. Acceptable recoveries were obtained for all samples. The RSD for the

replicate analyses in the stability study indicated that the method is capable of RSD values less than 5% in a relatively clean groundwater matrix. Chlorine isotope ratios can be used to define statistical process control limits for use as an additional analyte identification tool.

The origin of perchlorate in the environment can be determined by measuring the isotope ratios of ^{35}Cl : ^{37}Cl . This ratio is different for human-made perchlorate and naturally occurring perchlorate and can be used to trace the source of the pollution. This may be important if legal and liability aspects are involved [330].

4.2.4.8 Detection of AP in Urine

Perchlorate ion that is ingested with food or water is quickly excreted in the urine. Several studies have been conducted studying perchlorate retention in the body and perchlorate excretion in urine. Analytical methods for the analysis of perchlorate in urine include ion chromatography coupled with electrospray tandem mass spectrometry [331] and electrospray ionization mass spectrometry [332].

Because perchlorate competitively inhibits iodide uptake, the presence of larger quantities of iodide may minimize the impact of perchlorate on thyroid function. A method to quantify perchlorate, nitrate, and iodide in human urine, milk, serum, blood spots, amniotic fluid, and infant formula using IC-ES-MSMS has been published [333].

4.2.4.9 Detection of AP in Food Stuff

For the latest findings regarding the determination of perchlorate anion in vegetable foods by ion chromatography-tandem mass spectrometry see [334].

A simple, selective, and sensitive method for quantifying perchlorate in milk powder and milk used hydrophilic interaction chromatography combined with tandem mass spectrometry (HILIC-MS/MS). This method used an Inertsil HILIC column (150 mm $\times$ 3.0 mm, 3.5 μm) with a mobile phase consisting of methanol and 0.1% formic acid (ratio of 60:40 by volume) [335]. The detection was performed by MS/MS via electrospray ionization. Linear calibration curves were obtained in the concentration range of 2.00×10^{-2} to 8.00 $\mu\text{g/g}$ and 4.00×10^{-1} to 20.0 $\mu\text{g/L}$ for perchlorate in milk powder and milk, respectively. The MDL was 4.00×10^{-3} $\mu\text{g/g}$ for milk powder and 8.00×10^{-2} $\mu\text{g/L}$ for milk. The recoveries of perchlorate in spiked milk powder and milk were all >90%. This method can be applied to the quantitative determination of perchlorate in milk powder and milk.

4.2.4.10 Detection of AP in Biological Samples

A method for measuring perchlorate in biological samples that uses ion chromatography (IC) coupled with conductivity detection has a detection limit for perchlorate in the fluids and tissues of rats of 3–6 ng/mL and 0.007–0.7 mg/kg, respectively [336].

4.2.4.11 Analysis of AP in Other Non-Biological Matrices

EPA method EPA/600/R-01/026 was used for an interlaboratory validation of methods for the determination of perchlorate in fertilizers [337]. The ground fertilizer material was either leached with deionized water to dissolve any perchlorate salt (in the case of minimally soluble fertilizers, e.g., supertriplephosphate or timed-release products) or simply dissolved in the case of highly soluble fertilizers (e.g., urea, NaNO_3 , or KCl). The resulting aqueous solution was then subjected to IC with suppressed conductivity detection. Four laboratories applied the method to field samples using 48 different fertilizer products and to seven quality control samples prepared by the EPA. Recovery (81–111%) was demonstrated on spikes of known concentration and a preliminary assured reporting level was determined for each fertilizer matrix by each laboratory. All the laboratories used Dionex IonPac AG16 guard and AS16 separation columns with NaOH or KOH as eluent. The results indicated that perchlorate was not detectable in any real-world fertilizer products (including synthetic fertilizers) that were not derived from Chilean caliche. Perchlorate was detected in only five of the products (concentrations ranging from 1800 to 4200 $\mu\text{g/g}$).

Perchlorate in fertilizer can be analyzed using an IC with gel columns [338] and with other methods. In addition to IC, the fertilizer was analyzed for perchlorate using complexation electrospray ionization mass spectrometry and high field asymmetric waveform mass spectrometry [339].

4.2.4.12 Analysis of AP in Composite Propellants

A potentiometric method that is applicable to the analysis of casting powders and propellants first reduces all perchlorate to chloride via combustion in a Parr bomb, with subsequent titration of chloride ion taking place with a Beckman model K automatic titrator [340]. It was claimed that this procedure reduces the operator variability experienced in the traditional Mohr titration method.

AP in solid propellant slurries can be analyzed using a simple and rapid non-aqueous potentiometric titration method [341].

4.3 Thermal Stability and Decomposition of Ammonium Perchlorate

The thermal stability and the decomposition of AP is important for the storability of AP-based solid propellants under a wide range of environmental conditions and for the maximum temperature tolerated when curing freshly cast grains in an autoclave. The thermal stability also determines the burning rate of AP-based propellants. Catastrophic fires in the vicinity of AP storage areas or rocket motors containing AP-based propellants subject the propellant to cook-off conditions and the thermal stability of AP determines if this condition is survivable. The transition from controlled, slow thermal decomposition to uncontrolled, rapid deflagration is a critical point of no return.

It depends on a variety of factors that must be completely known in order to safely manufacture, store, transport, and use this oxidizer.

One peculiar feature of the thermal decomposition of AP is that a solid residue is formed, which is chemically equivalent to the original material. Attempts to explain this phenomenon, which is of inherent chemical and practical interest, have caused many investigators to concentrate their examinations to the low-temperature region below 523 K (250 °C). AP is stable at room temperatures but decomposes at about 423 K (150 °C). The residue, however, remains quite stable below 523 K (250 °C) unless it is rejuvenated by recrystallization, grinding, or sublimation. In line with these decomposition reactions, AP undergoes dissociative sublimation. The chemical analysis of gaseous products is rather complex and is dependent on many factors including temperature. Freshly sublimed AP has a shorter induction period for decomposition compared to ordinary AP. It may contain some decomposition products that catalyze the decomposition.

Several summary publications regarding the thermal stability of AP are available. The best summary published to date is one by Boldyrev, who has been working on AP decomposition for over 30 years [17]. Boldyrev's review, containing 202 literature references, is the most comprehensive summary of literature data on thermal decomposition of AP that has been published in several decades. It is a very valuable source of information for further in-depth study of the thermal decomposition of AP. The mechanism of thermal decomposition and various factors which influence the thermal decomposition of AP are discussed in detail with numerous references to published literature.

Boldyrev's [17] summary updates and supersedes an earlier excellent summary by Jacobs and Whitehead [16]. This contained a fantastically high number of useful citations (419 references) and remains an excellent source for the interested reader and researchers alike. It also supersedes the summary published by Keenan and Siegmund in the same year [342].

Other summaries on AP decomposition are in book chapters [343, 344]. Two additional very detailed reviews discuss the effect of particle size in coarse AP on decomposition mechanisms and burning rates [345, 346].

The thermal decomposition of AP goes through two stages. The LTD at 420 to 600 K is an autocatalytic nucleation and growth process. In this regime, a crystallographic phase transition at 513 K complicates matters further. Reaction rates just above 513 K are noticeably slower than rates immediately below this temperature. The solid product of this low-temperature reaction makes up about 70% of the initial mass and is chemically identical with the initial reactant but has an increased surface area. The HTD above 600 K does not leave any residue. This reaction may be accompanied by sublimation if the pressure is low enough.

In addition to a comprehensive summary of the thermal decomposition of AP, NH_4ClO_4 , this section of the book also contains a sub-section on the thermal decomposition of the much less stable ammonium chlorate, NH_4ClO_3 . This compound can

be found as a contaminant in AP and has been the cause of numerous accidents in fireworks.

4.3.1 Stoichiometry and Thermodynamics of AP Thermal Decomposition

The decomposition of AP is characterized by two parallel processes: an irreversible and destructive reaction and dissociative sublimation in a reversible equilibrium situation. At moderate temperatures, the dissociative sublimation can be neglected due to the low vapor pressure of perchloric acid, which is one of the dissociation products. At high temperatures (523–773 K = 350–500 °C), and without trapping the dissociation products, the role of sublimation becomes more significant.

The auto-decomposition of AP results in a mixture of reaction products, the exact composition of which depends on the reaction conditions (adiabatic versus isothermal, pressure) and on the absence or presence of contaminants and potential catalysts. Chemical analysis of the reaction products does not always agree with thermodynamic equilibrium predictions.

Figure 17 shows the theoretical adiabatic temperature of complete AP decomposition under equilibrium conditions and constant volume as a function of loading density.

Figure 17: Adiabatic flame temperature of AP decomposition.

The simplest decomposition equation would be:

$$\begin{aligned}
 280.9 \frac{\text{kJ}}{\text{mol}} \text{NH}_4\text{ClO}_4 &= 2390 \frac{\text{kJ}}{\text{kg}} \text{NH}_4\text{ClO}_4 \\
 2 \times -295.767 &= 3 \times -285.830 + 2 \times -92.31 + \Delta H_{\text{react}} \\
 -480.387 &= -857.49 - 184.62 + \Delta H_{\text{react}} = -1042.11 + \Delta H_{\text{react}} \\
 \Delta H_{\text{react}} &= 1042.11 - 480.387 = 561.723 \frac{\text{kJ}}{\text{FW}} = 280.86 \frac{\text{kJ}}{\text{mol}} = 2390 \frac{\text{kJ}}{\text{kg}} \\
 \text{AP } M &= 117.489 \frac{\text{g}}{\text{mol}} = 8.5114 \frac{\text{mol}}{\text{kg}}
 \end{aligned}$$

but that is not always what the chemical analysis of the reaction products shows. HCl can dissolve in water as soon as the water condenses in the combustion bomb. This forms a saturated aqueous solution of hydrochloric acid. Room-temperature reagent-grade aqueous HCl typically contains 37 mass-% HCl.

The theoretical adiabatic flame temperature at atmospheric pressure is 1385 K (1112 °C). HCl and O₂ form a pressure-dependent equilibrium

Other measurements suggest that the decomposition of AP at 101 and 6895 kPa (14.7 and 1000 psia) proceeds according to the following equations:

4.3.2 Experimental Studies of AP Thermal Stability and Decomposition

There are many experimental methods to study the thermal stability of AP and AP-based propellants including DTA, TGA, DSC, volumetric gas evolution, Raman spectroscopy, and mass spectrometry. The volatile pyrolysis products can be analyzed using rapid-response analytical instruments such as FTIR or mass spectrometers to detect and identify intermediates of the decomposition reaction. The rate of heating is one of the test variables. Heating rates in DTA, DSC, and TGA are generally slow (1–10 °C/min.). Unfortunately, when looking at existing literature, information on heating rates is not always provided when summarizing the onset of exotherms or other endo/exothermic phenomena. More rapid heating for flash pyrolysis studies can be achieved by heating the sample with a laser or placing a thin film on a resistance-heated metal foil (T-jump pyrolysis).

The thermal decomposition of AP is sensitive to catalysis by contact with container materials in which it is contained during the DTA or DSC test. A common DSC crucible material is pure (soft) aluminum. Pure aluminum has little or no catalytic effect on AP decomposition, but some aluminum alloys (“Duralumin” similar to AA2024, which contains 4.4% copper) and stainless steel cause accelerated decomposition [347]. Comparing results obtained in aluminum and with a mica dish, the DTA thermograms obtained with ‘as received’ and doubly recrystallized AP were essentially the same.

4.3.3 Slow AP Decomposition

There are many techniques available to study the slow decomposition of AP and similar ammonium salt oxidizers. The methods used for the study of AP decomposition include:

- DTA
- DSC
- TGA
- Gas evolution measurements
- IR spectrometry
- Raman spectrometry

To organize the literature on AP decomposition we have subdivided the material by the rate of decomposition, slow decomposition at temperatures below and near the melting point, and rapid decomposition at temperatures that are closer to those encountered in rocket motors.

Other subdivisions can be created, such as by the purity of the AP sample and the presence or absence of catalysts or inhibitors. There are many AP decomposition studies that used single crystals with direct observation, where the progression of decomposition sometimes documents itself by the initially clear crystal turning opaque as the crystal lattice changes and with the evolution of embedded bubbles. The decomposition often spreads visually, which is evident from crystal defects that act as nuclei for the start of the reaction.

Bircumshaw and Newman [348, 349] observed that when AP thermal decomposition occurs in the orthorhombic crystal phase, the mass conversion rate in the orthorhombic crystal phase was faster than in the cubic crystal phase. At temperatures below the normal AP phase transition temperature, the orthorhombic crystal phase decomposition process had a variable induction period before decomposition started.

The low-temperature orthorhombic crystal phase decomposition process produces AP particle porosity, leading to a mechanism for an increased rate of mass conversion to gaseous products [350]. High-speed cinematography of burning coarse AP crystals demonstrated that the pore formation and the pores became the source of decomposition gaseous products. Microscopic observation of heated crystals could see clouds of small (about one micron) particles, which are described as nuclei. These nuclei were non-uniformly distributed but moved and joined up to form reactive centers. Reactive centers grew to a maximum size of about 2 microns and then ceased to grow. Microscopic amounts of liquid containing water were contained in the reactive centers. The maximum size for reactive centers was assumed to be inhibited by local rising water content from AP decomposition. At 507 K (234 °C) nuclei had maximum linear velocity along the main orthorhombic crystal axis in the range of 7 to 10 microns per minute. Smaller nuclei moved faster than larger ones. Activation energies for nuclei movement were determined as being 130 kJ/mol (31 kcal/mol) along the orthorhombic crystal longitudinal axes and 138 kJ/mol (33 kcal/mol) in the

transverse direction. The transverse velocity of nuclei was roughly about one-tenth that along the main orthorhombic crystal axis. Natural and acquired trace impurities are most likely present at the nuclei responsible for porosity formation. Rates of porosity production in coarse oxidizer during solid propellant combustion influences burn rates, burn rate pressure exponents, the violence of slow cookoff trials, and even erosion rates under high-velocity erosive burn recession conditions.

Phase changes and decomposition of AP take place simultaneously. Most investigators have identified only one polymorphic phase change in the range between 503 and 523 K. One investigator suggested that an irreversible second-order phase transition takes place at 513 K and the reversible orthorhombic-cubic transition takes place at 523–543 K [351]. The irreversible second-order transition was said to be the real cause for the change in the decomposition rate at 513 K. Visual observation of the orthorhombic to cubic transition in a single crystal revealed that the transition was accompanied by the appearance of a large number of surface cracks and an apparent sudden increase in surface reaction (i.e., growth of reaction nuclei). One needs to determine whether the amorphous layer, which first appears to form on the large crystal surface, is transformed into crystallites or decomposes (or sublimes), leaving behind the observed structures.

Over the course of six years, from 1962 through 1967, and under the sponsorship of AFOSR with two consecutive contracts, Atlantic Research Corp. has conducted a detailed investigation on the deflagration of high-energy solid oxidizers containing the perchlorate anion [352, 353]. This included AP, hydrazinium(2+) diperchlorate (see *Encyclopedia of Oxidizers*, chapter *Hydrazinium Salts*), and hydroxylammonium perchlorate (see *Encyclopedia of Oxidizers*, chapter *Hydroxylammonium Salts*).

AP is stable at room temperature but decomposes at measurable rates over a wide temperature range from 473 to 713 K (200 to 440 °C). It undergoes an autocatalytic decomposition between 473 and 573 K (200 °C and 300 °C), which is limited to about 30% decomposition and is often called LTD. At 573 to 703 K (300 to 430 °C), the HTD takes over. This reaction is not autocatalytic. Concurrently with these decomposition reactions, AP also undergoes dissociative sublimation both in the LTD and HTD regions and ions can be detected in the vapor phase. At about 673 K (400 °C), AP decomposes very rapidly and suddenly explodes after a short induction period.

A mass-spectrometric investigation of the products of thermal decomposition of AP placed the furnace with the decomposing AP near the ion source of a mass spectrometer [354]. At 384–393 K (111–120 °C), the main products were NH_3 , HCl , Cl_2 , O_2 , and small amounts of nitrogen oxides among the products of decomposition. The molecular complex NH_3HClO_4 was not found. Its existence was postulated in previous investigations of the thermal decomposition of AP. Analyzing the results obtained, Heath and Majer concluded that the primary products of the thermal decomposition of AP are ammonia and perchloric acid. It is not clear why they excluded the possibility of secondary reactions in the gas phase. The presence of HClO_4 , NO , NO_2 , O_2 , and Cl_2 among the products under high vacuum conditions indicate the occurrence

of a parallel reaction proceeding in the condensed phase. However, the high vacuum decomposition products may have contained significant quantities of NO_2 and HCl in addition to the usual major products given as Cl_2 , N_2O , O_2 , and H_2O . The reported product distributions were semi-quantitative, however, because only uncorrected ion intensities were given. Since each AP sample was pyrolyzed in a sequence of increasing temperature steps, the respective effects of time and temperature were uncertain. The appearance of somewhat higher decomposition rates under high vacuum, however, was apparent since their sample was entirely consumed by decomposition and sublimation below 200°C . An additional contribution of their study involved determinations of the 70 eV HClO_4 fragmentation pattern and the effects of a hot platinum filament on the heterogeneous decomposition of HClO_4 .

The decomposition of AP at low pressures and constant temperatures was measured using a TOF mass spectrometer [355]. Chlorine concentration was measured as a function of time and sample temperature. The pyrolysis was conducted under high vacuum conditions where secondary reaction effects are minimized. Perchloric acid and argon were used as internal standards to calibrate the ion intensity, but of course, HClO_4 was also an intermediate decomposition product. The activation energy for sublimation was 89.96 kJ/mol (21.5 kcal/mol). Only small amounts of nitrogen and OClO were detected. Ions that were expected but not found were NH_4^+ , ClO_4^+ , $\text{NH}_4\text{ClO}_4^+$, $\text{HClO}_4\text{HClO}_4^+$, NOCl^+ , N_2O_4^+ , and Cl_2O_3^+ . The intensities of peaks attributed to HClO_3^+ , HClO_2^+ , HClO^+ , and ClO^+ were approximately proportional to HClO_4^+ and agreed with data reported by other investigators. The data indicated that the decomposition stoichiometry can be described by

The same authors later studied the rapid thermolysis of AP using a laser as the heat source. The acidity that develops during AP decomposition can be used as an indication of changes occurring in the material [356, 357]. AP becomes acidic at about 493 K (220°C) and reaches a maximum of acidity at 513 K (240°C). The acidity was not caused by HCl , HNO_3 , or HNO_2 . Therefore it was most likely caused by free HClO_4 . The effects of particle size, ambient atmosphere, additives, and prior irradiations by X-rays or UV on AP decomposition were studied using acidity as an indicator. Metal chlorides, chromic oxide, potassium chromate, or potassium bichromate added as contaminants accelerated the decomposition of AP.

TGA, DTA, XRD, gas chromatography (GC), and MS were used to study the decomposition of AP crystals which were recrystallized from acidic solutions or water and were found to have a number of defects [358, 359]. Surprisingly, the rate of thermal decomposition of AP with a normal structure is faster than that of AP with a defective structure. HClO_4 accelerates the thermal decomposition of AP. When AP was pulverized, its defective structure changed to a normal structure and a small amount of HClO_4 was formed. When AP was heated the defective crystal structure gradually changed to a normal one, its volume increased, and the formation of HClO_4

became noticeable. At temperatures beyond the transition point, a first exotherm occurs, but following this step, the residual AP decomposed exothermally at higher temperatures. NiO accelerated the thermal decomposition of AP and the burning velocity of AP/polybutadiene propellants.

The influence of various parameters on the thermal decomposition of AP at low temperatures revealed that there is a critical value for the particle size on either side of which the reaction rate decreases [360]. An electron transfer mechanism (involving point defects) is supposed to account for decomposition. A proton transfer mechanism leads to sublimation. The effect of aging the crystals at room temperature in vacuo or at 383 K in air resulted in a marked decrease in the rate of gas release. This was attributed to healing of crystal defects by annealing, thus giving fewer nuclei where decomposition starts.

The slow isothermal decomposition of AP single-crystal sections at a relatively low temperature of 483 K (210 °C) was studied using cleaved sections of large single crystals grown from a water solution [361]. Crystals heated isothermally for several hours at 483 K (210 °C) (without igniting) turned optically opaque. This information was later used in the interpretation of the crystal appearance near the flame front in quenched and partially burned crystals.

When heating AP in a constant volume apparatus at a varying mass of AP : volume ratios and measuring the pressure at a constant temperature, AP decomposes each time to a point corresponding to a constant pressure at a particular temperature (e.g., 212 kPa at 423 K) [362]. This indicates an inhibition of thermal decomposition of AP by the products. The extent of decomposition varied from 73% to 1% depending on the mass of AP : volume ratio. Water was found to have a pronounced retarding effect, increasing the induction period and decreasing the pressure at which decomposition ceases. It was theorized that chlorine oxides such as Cl_2O_6 and Cl_2O_7 play a role in the decomposition mechanism. The latter is the anhydride of HClO_4 .

The kinetic constants of AP decomposition in the range from 469 to 553 K (196 to 280 °C) were measured [363]. At the phase transition temperature, only k_2 (the constant connected with the acceleration of the process) changed, whereas k_1 continued to increase with the temperature. As a by-product of the decomposition at both 20 mm Hg and at atmospheric pressure, a condensate was obtained on a cool (about 50 °C) quartz plate and identified as pure (sublimed) AP.

Large single crystals of AP thermally treated for 40 minutes at 499 K (226 °C) at 20 mm Hg pressure and then examined under the SEM revealed rectangular holes which make up the decomposition nucleus [364]. The holes have the shape of the *m*-face with edges running parallel to the edges of the *m*-face. They are arranged in a disk-like pattern and eventually develop into a porous residue. Furthermore, the decomposition seems to occur in layers with the size of the holes becoming smaller and smaller with increasing depth. When the decomposition is stopped after different lengths of time, it could be seen that, in the case of pure AP, the

decomposition interface advanced linearly with time into the crystal. Similar tests were then performed with AP that had been doped with MnO_4^- ions.

An investigation of the thermal decomposition kinetics of AP in terms of weight loss and gas release in the 593–726 K (320–453 °C) range measured total decomposition kinetics up to 663 K (390 °C) and kinetics of the initial fast stage from 668–726 K (395–453 °C) [365, 366]. In the first stage, the initial reaction rate increased more rapidly than the autocatalytic effect. The reaction time at temperatures above 573 K (300 °C) was comparable with the time of heating and thus the kinetics measurements were not reliable enough. The reaction rate in the second stage also increased and was almost independent of the degree of conversion. The velocity may be expressed by the kinetic equation of zero-order $da/dt = k_3$. The value of k_3 depends on temperature according to the equation

$$k_3 = 5.8 \times 10^6 \exp(-32,500/RT) \text{ s}^{-1}$$

in the temperature range between 533 and 663 K (260 and 390 °C). The decomposition kinetics of AP at 668–726 K (395–453 °C) were studied by placing 10 mg AP on an electrically heated Ni-Cr plate under nitrogen at 26.58 kPa (200 mm Hg) pressure. The course of the initial stage could be described with 1st order kinetics. The temperature dependence can be expressed by the equation

$$k_1 = 10^9 \exp(-32000/RT) \text{ s}^{-1}.$$

This equation is identical with that obtained for the temperature range 573–553 K (200–280 °C). The linear pyrolysis method using rectangular molded specimens of AP pressed against a hot bar evaluates the dependence between the temperature T_0 and the rate of decomposition u . The plots of $\log u$ versus $1/T_0$ revealed two different regions; at $T_0 > 773$ –823 K (>500–550 °C), the pressure on the specimen exerts no remarkable influence; the material of the hot bar may accelerate the decomposition (such as several metals or their oxides). The flame appeared only when the specimen was pulled back from the bar so that a small gap was formed between them. The rate of regression at 553–773 K (280–500 °C) on a mica plate under atmospheric pressure can be expressed by the equation

$$u = 2.5 \times 10^6 \exp(-30,200/RT) \frac{\text{mm}}{\text{s}}.$$

This corresponds to $k_0 = 5.9 \times 10^6 \text{ s}^{-1}$. The decrease of decomposition rates >573 K (>300 °C) was explained in terms of structural changes such as dislocations and defects of the crystal lattice. The results revealed that the kinetic reaction parameters (k_0 and E) remained constant over a wide temperature interval (473–723 K = 200–450 °C). However, above 573 K (300 °C), the fraction of material decomposing during the first fast stage of the reaction decreased.

The slow rate of decomposition of AP depends strongly on the conditions under which the AP was recrystallized and on the age of the crystals. The reactivity of AP as

a function of the method of preparation and the age of the material was studied using constant volume isothermal decomposition [367]. Samples were prepared by:

- (1) dissolving analytical grade AP in H_2O at 333–343 K (60–70 °C) and allowing it to recrystallize by cooling to room temperature;
- (2) recrystallizing AP from a saturated aqueous solution cooled to 278 K (5 °C); and
- (3) growing single crystals from a saturated aqueous solution at 318 K (45 °C), then cooling at a rate of 0.1–0.01°/d.

The slow decomposition of AP was studied at 503, 573, and 673 K (230, 300, and 400 °C). Sample (2) was more reactive than sample (1) at all temperatures studied. Sample (2) and sample (3) sublime more readily than sample (1), which was corroborated by DTA measurements. Isothermal decomposition of freshly prepared and aged samples of (1) at the three temperatures indicated that during the first seven days after growth definite desensitization occurs followed by a marked increase in reactivity after 15 days.

AP sometimes needs to be modified to prevent or reduce the risk of inadvertent reignition of extinguishable solid rocket motors. Two methods were found that could eliminate or reduce the exothermicity of propellant grade AP exposed to temperatures of 350–390 °C during soakback [368]. One was a thermal pre-treatment and the other involved an additive. Prebaking AP eliminates the first exotherm and facilitates AP to be used in extinguishable rocket motors without the potential of unintentional reignition of the propellant grain. It was found that AP (in which this first exothermic peak was eliminated) could be prepared by heating the propellant grade AP to 638–663 K (365–390 °C) for several minutes and then allowing it to cool. Furthermore, this exothermic peak was eliminated via the pre-heating technique, even when the fluorocarbon polymer binder was in contact with the AP. This technique for preventing the first exotherm was successful in all samples of AP tested; the samples varied in particle sizes and were from several sources. Another method to prevent reignition was to add several percent of an inert ammonium salt to the AP.

The decomposition of AP in the gas phase at elevated temperatures was studied by allowing the vapor from a sample of subliming AP to pass through a secondary furnace maintained at a higher temperature than that of the subliming AP [369]. The reaction occurring in the secondary furnace was monitored using a pin-hole leak connected to a mass spectrometer. The effects of temperature and the addition of diluent gases were studied and the major products were identified, such as H_2O , O_2 , HCl , N_2O , NO_2 , Cl_2 , NH_2Cl , and NH_3 . Ammonia addition reduced the concentrations of all products except NH_2Cl , which increased. The early literature discussing with AP thermal decomposition up until 1968 was summarized in a review article [342, 370] (see [371, 372]).

In order to avoid secondary reactions and to analyze primary decomposition products, the AP crystal and the analyzing mass spectrometer have to be close-coupled. This is possible with an experimental gas sampling system that approximates a collision-free molecular beam [373]. Results with this system indicate

the occurrence of an exothermic surface reaction with ClO_2 as a major product resulting from the pyrolysis of AP between 473 and 673 K. Analyzing the off-gassing during AP decomposition with a mass spectrometer helps to identify the first and intermediate steps of the decomposition reaction [374].

The kinetics of AP solid state thermal decompositions between 473 and 573 K (200 and 300 °C) were measured using both single crystals and pressed pellets [159]. Kinetic analysis of the TGA decomposition curve by a non-linear least-squares computer program revealed that **(1)** the decomposition consists of four distinct stages, **(2)** the major part of the entire reaction ($0.01 < \alpha < 1.00$, where α is the decomposition fraction) can be described by an Avrami equation, **(3)** the so-called [induction period] involves a linear process plus an exponential process and involves only the first 1% of the total decomposition, and **(4)** the induction period is usually preceded by desorption of previously adsorbed species. The inward growth of surface nuclei is a linear process. Branching of surface nuclei along preferred crystallographic directions leads to exponential growth. This was confirmed by the microscopic observation of decomposing AP crystals under a hot stage microscope. In addition to this, the electrical conductivity of crystals was measured while the decomposition was in progress.

If FTIR is used, ordinarily the decomposition products of AP and other oxidizers are analyzed using their IR absorption when the beam transits the sample. A different IR technique uses the surface reflection of a decomposing AP crystal to observe solid-solid phase changes or decomposition products that accumulate on the surface [375]. The infrared spectra of the surfaces of AP crystals while being heated up to 250 °C have been obtained using internal reflectance spectroscopy. The crystal transformation from rhombic to cubic can be observed in this manner.

Using a TOF mass spectrometer and a probe that sucks species off the surface of decomposing AP crystals, it was attempted to identify the first products that leave the crystal surface at the very beginning of the decomposition process [376]. The species of most concern, HNO ($m/e = 31$), was found as a minor constituent by both high and low-resolution measurements at temperatures above 353 K (80 °C). This was confirmed by the strong reduction of $m/e = 31$ when deuterated AP instead of regular AP was decomposed because DNO occurs at $m/e = 32$. It is considered highly improbable that HNO could have occurred due to reactions other than surface thermal reactions. High-resolution spectra were used to separate the atomic oxygen (or doubly charged O_2) and NH_2 peaks at $m/e = 16$. Other hydrides of nitrogen were also found: NH_4 , NH_2 , and NH . No condensed-phase decomposition species were found at 80 °C or below. Perchloric acid, atomic chlorine, and all the simple chlorine oxides were found, but Cl_2 , HClO , HClO_2 , HClO_3 , or ClO_4 were not detected. Also not detected in the condensed phase were N_2 , N_2O , and NO_2 . The mass range monitored was from m/e 12 to 200. No parent $\text{NH}_4\text{ClO}_4^+$ ion was detected in any of the experiments.

The composition of chlorine-containing thermolysis products during TGA in the temperature range 160–220 °C at atmospheric pressure was measured under conditions of equilibrium of the decomposing AP with the decay products in the

gaseous phase [377]. Products were analyzed using potentiometric titration and UV spectrophotometry to determine the concentration of free chlorine, chloride-ions, and the sum of oxychloro-anions and perchloric acid.

The heat effect of the first exotherm of AP decomposition was $84.3 \text{ cal/g} = 9.9 \text{ kcal/mol} = 41.4 \text{ kJ/mol}$ as determined by isothermal methods and $87.5 \text{ cal/g} = 10.3 \text{ kcal/mol}$ by programmed constant heating rate scanning methods [112]. The heat effect for the second high-temperature exotherm was $190 \text{ cal/g} = 20.3 \text{ kcal/mol} = 84.9 \text{ kJ/mol}$ as determined by DSC. Scanning operations were carried out at heating rates of 2, 4, 8, 16, 32, and 64 K/min . The activation energy derived from the equation $\log S/\Delta H$ versus $1/T$ was $94.6 \text{ kJ/mol} = 22.6 \text{ kcal/mol}$ for the first exotherm and $253 \text{ kJ/mol} = 60.5 \text{ kcal/mol}$ for the second exotherm. Isothermal decomposition of AP produced activation energy of 88.7 to 109.6 kJ/mol (21.2 to 26.2 kcal/mol). The values of the activation energy for the low-temperature and high-temperature exotherms were in close agreement with reported literature values.

During the decomposition of AP powder at 733 K (460°C) the following ions were observed using mass spectrometry: N_2^+ , NO^+ , O_2^+ , HCl^+ , N_2O^+ , and Cl_2^+ [378]. The rate of decomposition depends on the crucible material. Some crucible metals catalyze the reaction.

In addition to the study of isolated AP decomposition, some investigators looked at slow heating rates and isothermal AP decomposition in the presence and absence of a binder (PS) [379]. Thermal changes and activation energies associated with thermal decomposition of PS and AP and propellants were derived from DSC thermograms of PS, AP, and a PS/AP propellant. The AP endotherm started at $517 \pm 2 \text{ K}$ (244°C). The endothermic enthalpy change was calculated to be $10 \pm 0.3 \text{ kJ/mol}$ ($2.39 \pm 0.07 \text{ kcal/mol}$), which agreed well with other reported literature values. About 30% decomposition had already occurred in the low-temperature exotherm (LTE) during both scanning and isothermal operations, which was in accordance with TGA measurements. The total exothermic heat release of both LTE and HTE was estimated to be $1163 \pm 40 \text{ J/g}$ ($278 \pm 10 \text{ cal/g}$). The E_{act} for LTE and HTE in scanning operations were 94 kJ/mol (22.5 kcal/mol) and 253 kJ/mol (60.5 kcal/mol), respectively, which agreed fairly well with values using other techniques. The AP/PS propellant exotherm starts at a later stage than the first exotherm of pure AP.

TOF and high-resolution mass spectrometry of AP and its deuterated derivative were examined in an effort to identify some of the key decomposition species [246]. HNO (mass 31) was found as a minor component at temperatures above 353 K (80°C). It is considered highly improbable that HNO could have occurred by reactions other than surface thermal reactions. High-resolution spectra were used to separate O_2^{2+} and O^+ from NH_2 at mass 16. The presence of NH_2^+ was confirmed along with NH_4^+ , NH_3^+ , and NH^+ . HClO_4^+ , Cl^+ , and all the simple oxides of chlorine were found but Cl_2^+ , HClO^+ , HClO_2^+ , HClO_3^+ , and ClO_4^+ were not detected. Also not detected were N_2^+ , N_2O^+ , and NO_2^+ in the condensed phase. No undissociated parent $\text{NH}_4\text{ClO}_4^+$ was present.

The breakdown of the crystal lattice of AP in the 300–625 K range has been studied by laser Raman spectroscopy [121, 122]. A thorough study was then conducted to examine the decomposition of AP crystals as a function of temperature in the 300–625 K range, as a function of pressure in the 0–40 kbar range, and as a function of isomorphously incorporated K^+ ions in the catalytic level concentration. These results helped one to understand how the oxidizer lattice is destabilized and begins to decompose. Detailed examination of the external and internal modes of the perchlorate ion revealed that the onset of essentially unhindered tumbling of the ClO_4^- ion may be intimately tied to the decomposition of AP. The frequency and linewidth of the ClO_4^- bending modes can be used as a crystal [thermometer]. The effect of K^+ as an isomorphous dopant in the crystal lattice is to permit the ClO_4^- ion to tumble at a lower temperature (addition of 0.8% K^+ produced a 10–15 K lowering in the tumbling temperature) and thus decompose at a lower temperature. Pressure effects on AP decomposition at 300 K show normal behavior. Pressure does not play a significant role in AP crystal decomposition. All vibrational modes found in AP from 40 cm^{-1} to 3500 cm^{-1} (including several not previously reported ones) were assigned, insofar as possible.

A non-confined AP single crystal was placed in a flow of heated N_2 gas and the temperature was regulated to $\pm 2\text{ K}$ using the flow rate. Repetitive Raman spectra were recorded [242]. Notable decomposition was observed beginning at 475 K. The broadening of the ClO_4^- bending modes without broadening of the A_1 stretch may have resulted from the onset of essentially unhindered rotational motion of the ClO_4^- ion. Two very weak previously unreported bands appeared in the orthorhombic phase at 715 and 543 cm^{-1} .

Hydrochloric and nitric acids accumulate during the thermal decomposition of orthorhombic AP in the solid. The concentrations of the acids increase up to a point where 15% degree of the AP has decomposed, after which they decrease again [380].

Samples of AP were aged at 373 and 523 K (100 and 150 °C) prior to heating them in a DTA-TGA. Depending on the aging time, AP revealed different decomposition characteristics [381]. The competing effects of sublimation and thermal decomposition could be separated using a special experimental arrangement. IR spectral investigations of decomposing AP produced information on intermediates formed during the decomposition of AP [382].

The thermal decomposition of solid, molten, and dissolved AP was examined over a wide temperature range from 488 to 658 K (215 to 385 °C) [383]. Over the entire temperature range, the decomposition appeared to proceed on a first-order reaction up to a point where 70% of the original AP was decomposed. In methanol solution, the rate of AP decomposition was similar to that of neat AP, but in aqueous solution, it was substantially slower than that of neat AP. Activation energies and frequency factors were listed for each condition. There may be some chemical interaction between methanol and AP.

Two different techniques, isothermal cook-off of small samples and gas evolution measurements with analysis using a chemiluminescence technique were used to

study the thermal decomposition kinetics of AP [384]. Most of the work was done on commercial propellant-grade AP powder in the 200 μm diameter particle size range. The cook-off tests were used to derive the critical temperatures (i.e., the minimum thermal runaway temperatures) for four sample sizes: 40 mg, 100 mg, 30 g, and 1200 g. The first-order decomposition rate coefficients at 438–603 K (165–330 °C) were between 1×10^{-6} and $3 \times 10^{-2} \text{ s}^{-1}$. Gas evolution rate measurements at 343–383 K (70–110 °C) produced rate coefficients that were several orders of magnitude smaller than any previous kinetic measurements. The activation energies for the two methods were almost identical. The cook-off rate data were fitted to the expression

$$k = A \exp\left[\frac{-E}{RT}\right] = 2.1 \times 10^9 \exp[-126400/RT]$$

where E is the activation energy in kJ/mol. The high-temperature rates obtained with commercial-grade AP at 513–603 K (240–330 °C) were several orders of magnitude higher than previous academic data for very pure AP. These data are, therefore, more applicable to industrial hazard analyses like those conducted in the aftermath of the Henderson explosion. The activation energy did not change at the temperature where AP undergoes a phase change of crystal structure at 513 K.

The decomposition of propellant-grade AP was studied under isothermal conditions in Argon at atmospheric pressure [385]. The weight loss of small samples was determined as a function of time, particle size, temperature, and crystal structure. The weight loss versus time curves has a low rate (slope) branch for the sublimation of highly porous residue which is generated during particle decomposition. The rate of partial decomposition depended on temperature, particle size, and crystal phase, whereas its extent changed with particle size and crystal phase. Sublimation appeared to be particle size independent. The interpretation of weight loss data was supported by optical and SEM of AP samples before and after thermal treatment. These data are needed in predicting the cook-off hazard of AP-based propellants.

The weight loss of small AP samples was measured as a function of time, temperature, and particle size [386]. The rate constants for two size fractions were obtained at six different temperatures. Activation energies for the decomposition of the fine and coarse size fractions were $133 \pm 4 \text{ kJ/mol}$ ($31.78 \pm 0.96 \text{ kcal/mol}$) and $110 \pm 1.7 \text{ kJ/mol}$ ($26.27 \pm 0.42 \text{ kcal/mol}$), respectively. The activation energy for the initiation period was $124 \pm 4.6 \text{ kJ/mol}$ ($29.62 \pm 1.1 \text{ kcal/mol}$).

The thermal decomposition of AP and AP-based composite propellants was studied using the simultaneous thermogravimetric modulated beam mass spectrometry (STMBMS) technique [387]. The main objective was to evaluate whether STMBMS can provide new data on AP decomposition that will provide sufficient detail on the reaction mechanisms and associated reaction kinetics to permit the creation of a detailed model of the thermal decomposition process with and without the presence of a binder. Such a model is a necessary ingredient to engineering models of ignition and for a slow-cookoff for these AP-based composite propellants. Results revealed

that the decomposition of pure AP is controlled by two processes: One occurs at lower temperatures ($513\text{--}543\text{ K} = 240\text{--}270\text{ }^{\circ}\text{C}$), produces mainly H_2O , O_2 , Cl_2 , N_2O , and HCl , and is shown to occur in the solid phase within the AP particles. Two-hundred μm diameter AP particles undergo decomposition in the solid phase, whereas $20\text{ }\mu\text{m}$ diameter AP particles react differently. The second process is dissociative sublimation of AP to NH_3 and HClO_4 , followed by the decomposition of, and reaction between, these two products in the gas phase. The dissociative sublimation process occurs over the entire temperature range of AP decomposition but only becomes dominant at temperatures above those for the solid-phase decomposition.

STMBMS was used to give a 3-D plot of z = peak intensity, x = mass, and y = temperature for slow AP decomposition [388, 389]. The data revealed that the overall decomposition is characterized by three distinguishing features: an induction period, an acceleratory period, and a deceleratory period. The major decomposition event occurs in the subsurface of the AP particles and propagates towards the center of the particle with time. The amount of total decomposition is dependent upon particle size and increases from 23% for $\sim 50\text{ }\mu\text{m}$ -diameter AP to 33% for $\sim 200\text{ }\mu\text{m}$ -diameter AP. This is one of the few methods that can separate the chemical and physical decomposition processes from one another.

Based on SEM results of the thermal decomposition of AP in the orthorhombic phase, the overall decomposition is characterized by three distinguishing features: an induction period, an accelerator period, and a deceleratory period [390]. The major decomposition event occurs in the subsurface of the AP particles and propagates towards the center of the particle with time. The amount of total decomposition is dependent upon particle size and increases from 23% for $\sim 50\text{ }\mu\text{m}$ -diameter AP to 33% for $\sim 200\text{ }\mu\text{m}$ -diameter AP. Gas formation rates were measured for the gaseous products and correlated with the visual observations.

AP decomposition is characterized by the occurrence of one major event that consumes up to 35% of the AP, depending upon particle size, and leaves behind a porous agglomerate of AP [391, 392]. The major gaseous products released during this event include H_2O , O_2 , Cl_2 , N_2O , and HCl . The major decomposition event follows three chemical pathways: The first and third channels are affected by the pressure in the reaction cell and occur at the surface or in the gas phase above the surface of the AP particles. The second channel is not affected by pressure and accounts for the solid-phase reactions characteristics of *o*-AP. The third channel involves the interactions of the decomposition products with the surface of the AP.

The decomposition of production-grade AP was studied under isothermal conditions in Argon at atmospheric pressure [393]. The weight loss of small AP samples was determined as a function of time, particle size, temperature, and crystal structure. The weight loss versus time curve had a characteristics sigmoidal shape for the irreversible partial decomposition of AP, which was followed by a low rate (slope) branch for the sublimation of the highly porous residue generated during partial decomposition. The rate of partial decomposition depended on temperature, particle size, and crystal phase, whereas its extent changed with particle size and crystal phase.

The thermal decomposition characteristics of AP and an AP-based composite propellant were measured at temperatures less than 543 K (270 °C) [394]. The studies utilized various techniques to evaluate the thermal decomposition of neat AP as a function of time, particle size, temperature, and crystal structure.

Kinetic measurements for the fine, medium and coarse size fractions of AP revealed that the kinetic parameters changed with particle size [395]. The correlation between particle size and kinetics may be one of the reasons for the scatter in the kinetic data as reported in the literature. In addition to particle size, temperature, and time, there also was an effect of the TCP coating on weight loss during decomposition.

The thermal decomposition of AN and AP was investigated using an accelerating rate calorimeter (ARC). The curves of the thermal decomposition temperature and pressure versus time for the two systems are obviously different. The kinetic parameters such as apparent activation energy and pre-exponential factor of the thermal decomposition of AN and AP were calculated and compared [396].

The isothermal decomposition and sublimation of large TCP-coated AP particles were studied in the temperature range 419–449 K (146–176 °C), where AP is in the cubic phase [397, 398]. The course of the reaction was followed by TGA by measuring the weight loss as a function of temperature and time. Upon phase transition, AP became more stable. The analysis of the weight loss curves yielded activation energies E_a of 85.0 and 146.2 kJ/mol (20.31 kcal/mol and 34.94 kcal/mol) and pre-exponential factors A of $5.48 \times 10^6 \text{ min}^{-1}$ and $1.20 \times 10^{13} \text{ min}^{-1}$ for the decomposition and initiation time, respectively, of cubic AP. Sublimation, in contrast to decomposition, did not show a break upon transition to the cubic phase. Weight loss data was analyzed using the same equation that was used for orthorhombic AP. The analysis yielded $E_a = 130.7 \text{ kJ/mol} = 31.25 \text{ kcal/mol}$ and $A = 5.95 \times 10^{10} \text{ h}^{-1}$ for the kinetic parameters. Sublimation rates were considerably smaller than decomposition rates allowing analysis of decomposition data without correction for weight loss due to sublimation. Decomposition and sublimation kinetics for cubic AP were used to calculate the decomposition and sublimation rates of cubic AP that was heated at constant rates. The TGA results were compared to those of DSC tests and applied to determine the time to cookoff of larger samples of AP-based propellants.

FTIR analysis identified species involved in the solid decomposition step and pointed toward the importance of the diffusion of species in the solid [399] (see [400] also).

Most of the work on the slow decomposition of AP was done in the 1960s and 1970s. However, this was not always with unequivocal results; some questions remained unanswered. It was, therefore, very welcome when a fresh approach to the study of AP decomposition was undertaken by Longuet and Gillard in 2009. The researchers repeated some of the earlier tests but used modern equipment [401] such as TGA/MS, SEM, and FTIR. The objective of this work was to clarify the differences observed in the literature in order to understand the detailed decomposition kinetic process of AP and to establish analytical laws to facilitate the prediction of the thermal behavior of AP.

They re-measured the influence of particle size, the nature of gaseous decomposition products, and the morphologic evolution of crystals during decomposition in the temperature range of 459 to 529 K (186–256 °C). Gaseous species produced during thermal decomposition were quantified and analyzed using TGA coupled with a mass spectrometer. The surface state of AP crystals was analyzed using FTIR in the diffuse reflection mode (instead of transmission). Reflectance IR analysis is an optically simpler technique (particularly for pulverized solids) compared to transmission IR and involves reflected IR coming from the surface of the sample, showing the evolution of species in the solid decomposition stage and the importance of the diffusion of species in the crystals from the core to the surface. The crystals were also examined by SEM after mounting them in a casting resin matrix (Araldite) and cutting them with a microtome in order to observe the cross-section of the crystals at various stages of decomposition.

The TGA mass loss curves of AP heated from 459 to 529 K over a period from 30 minutes to six hours show three typical periods, as demonstrated in Figure 18 and as already observed by earlier investigators:

- an induction period (I)
- an acceleration period (A)
- a deceleration period (D)

The time-temperature surface in the 3-D graph shows a dimple (valley) in the area of the phase change from orthorhombic to cubic phases around 518 K (245 °C).

In Figure 19, the rate of conversion measured by weight loss versus the degree of conversion of AP orthorhombic and cubic phases are illustrated in two separate graphs (top and bottom) for different isothermal experiments.

The sigmoidal forms of the TGA curves suggest that kinetic models like Prout-Tompkins (Eq. 1), Avramii-Erofeev (Eq. 2), or a generalized expression of Prout-Tompkins equation (Eq. 3) should be good candidates for modeling the decomposition process [402].

$$\frac{d\alpha}{dt} = Z \times \exp\left(\frac{-E_a}{RT}\right) \times \alpha \times (1 - \alpha) \quad (1)$$

$$\frac{d\alpha}{dt} = Z \times \exp\left(\frac{-E_a}{RT}\right) \times (1 - \alpha) \left[-\ln(1 - \alpha)\right]^{\frac{n-1}{n}} \quad (2)$$

$$\frac{d\alpha}{dt} = Z \times \exp\left(\frac{-E_a}{RT}\right) \times \alpha^b \times (1 - \alpha)^c \quad (3)$$

Figure 20 shows a comparison of the closeness of fit of predicted rates of conversion to the measured data (shown in green diamonds). As can be seen, the rate predicted from Eq. 3 gives the best fit to the data:

Figure 20: Fit of the rate of conversion as a function of the degree of conversion based on three kinetic descriptions. (Reproduced and modified from [399], with permission granted by P. Gillard on 28 June 2021.)

Legend: Eq. (1): Prout-Tompkins; Eq. (2): Avramii-Erofeev; Eq. (3): generalized Prout-Tompkins equation

The Arrhenius parameters were calculated for the two temperature regimes and were within the range of values found in the literature (80–150 kJ/mol).

Using SEM images of heated and cooled individual crystals it was possible to determine the propagation rate of the decomposition front for each temperature

of the orthorhombic phase. These rates were comparable with those observed by Kraeutle [403] on very large crystals in the temperature range of 494 to 504 K (221 to 231 °C).

The overall stoichiometry between 459 and 529 K (186 and 256 °C) can be represented by the equation

Based on FTIR in the diffuse reflectance mode, the following species were identified on the surface of AP crystals: NH_4^+ , ClO_4^- , ClO_3^- , and Cl^- . This result is consistent with observations by Peroni [404]. ClO_3^- and Cl^- were present as contaminants in the undecomposed commercial-grade AP. One of the intermediates of AP decomposition was identified as the ClO_4 free radical. The FTIR reflectance spectra of AP in the process of decomposing at 499 K (226 °C) were measured repeatedly over a period from 30 minutes to three hours and the spectra were superimposed, highlighting the IR absorption bands where the most pronounced changes were taking place (Figure 21).

Figure 21: Evolution of reflectance FTIR spectra of AP at different times during heating at 499 K (226 °C). (Reproduced and modified from [399], with permission granted by P. Gillard on 28 June 2021.)

The thermal decomposition characteristics of AP at 443 K (170 °C) were studied using a dry heating method at constant temperature and TGA with relatively large (gram level) sample sizes [405]. The results revealed that with increasing heating time, the mass loss of AP increased, and the maximum mass loss was reached in the second hour. The thermal decomposition processes of AP can be divided into three steps. The maximum mass loss was 32.19% and the maximum rate of reaction was 1.125 s^{-1} .

AP crystals that had been heated for a while at 443 K (170 °C) had an increased impact sensitivity.

The slow thermal decomposition of AP was studied by TGA/DSC/MS/FTIR simultaneous analysis [406]. The MS-FTIR spectra demonstrated that N_2O and NO_2 were the main gaseous products of the thermal decomposition of AP. There was also a competition between the formation reaction of N_2O and that of NO_2 during the process with an iso-concentration point of N_2O and NO_2 . The dependence of the activation energy on the degree of conversion indicated that the AP decomposition process can be divided into three stages, which are (1) autocatalytic, (2) low-temperature diffusion, and (3) high-temperature stable-phase reaction. The corresponding kinetic parameters were determined by multivariate non-linear regression and an updated mechanism of the AP decomposition process was proposed. The abstract did not mention the occurrence of HCl, which one would expect as a decomposition product of AP.

The slow thermal decomposition of AP was investigated by thermo-analytical techniques including TGA, differential thermogravimetry (DTG), and DSC in an inert atmosphere of pure nitrogen at heating rates of 5, 10, 15, 20, and 50 °C/min. [407]. As expected, the reaction front moved forward towards higher temperatures with an increase in sample heating rate. The maximum heat release of 623 J/g occurred at a sample heating rate of 10 °C/min. The decomposition of AP proceeded in two phases, with the LTD maximum decomposition rate peak appearing at 561 K (288 °C), and the HTD maximum rate of decomposition occurring at 703 K (430 °C). During the LTD temperature regime, only 28.2% of the material decomposed and the decomposition ceased for a while. In the HTD temperature regime, the remaining AP decomposes leaving no residue.

4.3.4 Rapid AP Decomposition

Rapid heating of AP more closely represents conditions experienced by AP crystals in a solid rocket motor. Rapid heating can be achieved with lasers or by placing a thin film of AP on a metal foil with low thermal mass that is very rapidly heated by passing an electrical current through it. Prior to the advent of lasers, AP and propellant samples were flash-heated with the focused light from an electric arc.

The orthorhombic phase of AP decomposes faster than the cubic phase. The overall rate of decomposition is dependent on the heating rate. In a rapidly increasing temperature environment, AP may not undergo thermal decomposition until temperatures reach considerably above the 513 K (240 °C) phase transition temperature. This is because the induction period for the AP LTD process had not yet lapsed during the period while the AP was at temperatures below the normal crystal phase transition temperature. With rapid heating, AP could decompose directly from the orthorhombic phase.

4.3.4.1 Flash Pyrolysis Studies of AP

The flash pyrolysis of AP was studied by kinetic time-resolved IR spectroscopy [408]. The absorption spectra of OH, ClO₂, ClO, NO, and NH were observed in the decomposition products. The relative concentration of each was provided for the period of 1000 μs following the initial photoflash. Absorption bands of ClO₂ and OH were the principal bands observed at 20 μs after the flash. NH₃ and ClO₂ appeared very rapidly but after 10 μs the ClO₂ completely disappeared and was replaced by ClO, which then slowly decayed and Cl₂ and HCl go on to form. Flash-heating of ClO₂/NH₃ mixtures produced similar results. The flash pyrolysis data support the theory that the initial step in the decomposition of AP leads to the formation of ammonia and anhydrous perchloric acid. Subsequent reactions consist of the high-temperature oxidation of ammonia by perchloric acid.

4.3.4.2 Laser Pyrolysis Studies of AP

Sudden heating of AP crystals by laser may actually split the crystals by local heating before they ignite. AP crystals are transparent to the 694.3 nm radiation of a ruby laser. Therefore, to absorb more of the light when studying laser ignition of AP, one has to mix in absorbent material such as charcoal or metal oxides. Because the opaque substrate heats faster than the AP, ignition occurs at the substrate-AP interface and it is a heterogeneous reaction. The gases evolved during laser pyrolysis of opacified AP contained within the mass spectrometer were analyzed by mass spectrometer [409, 410]. The opacifiers were carbon black, copper chromite, iron(III) oxide, and manganese(IV) oxide. Shortly after zapping the propellant with a millisecond laser pulse, all the major decomposition products appeared at the same time. Perchloric acid and ammonia had short lifetimes. Relative ion intensities indicated that there was always a stoichiometric deficiency of HClO₄ compared to the amount of ammonia present. Chlorine is a major product when HClO₄ adsorbed on AP crystal surface decomposes, and OClO is a product that then decomposes on a catalyst.

AP and other solid propellant ingredients were pyrolyzed within the low-pressure ion source of a Bendix TOF mass spectrometer [411]. Pure AP is strongly absorbed at 10.6 μm. Input power densities applied were between 5 and 250 cal cm⁻² s⁻¹ = 21 and 1046 W/cm² for 0.1–5 s square pulses. The dissociative evaporation produced NH₃ and HClO₄ which appeared within 2 ms. The •ClO₃ radical was also observed in significant quantities [412]. It can also become trapped in AP crystals [114].

Mass-spectrometric and linear regression rates derived from CO₂-laser pyrolysis of pressed AP pellets at incident fluxes Q ranging from 105 to 16736 W/cm² (25 to 4000 cal cm⁻² sec⁻¹) and pyrolysis product evolution-rate histories were obtained in vacuo by time-resolved (5 ms) mass spectrometry during (a) transient heat-up and (b) subsequent quasi-steady vaporization (QSV) [413]. Vaporization induction times were obtained for (a); these, coupled with heat-transfer approximations neglecting thermochemical heat release, indicated that optical absorption at 10.6 μm dominated over conduction for $Q \gg 300$ cal cm⁻² sec⁻¹. Depending on the flux density, the AP under-

went (a) exothermic high-temperature condensed-phase decomposition (CPD) yielding H_2O , HCl , Cl_2 , O_2 , N_2O , NO_2 , and N_2 in variable proportions, or (b) endothermic dissociative-evaporation (DE) yielding NH_3 and HClO_4 . It was concluded that preferential desorption of NH_3 *in vacuo*, with net accumulation of adsorbed HClO_4 , occurred during transient heat-up and onset of CPD. However, preferential decomposition of adsorbed HClO_4 occurred during QSV when CPD was significant. CPD was the dominant mode of QSV at moderate Q for $200 < Q < 400 \text{ cal cm}^{-2}\text{sec}^{-1}$.

The decomposition of AP was initiated with a pulsed excimer laser at very low pressures (0.00001 mm Hg) [414]. Transient emission spectra from nascent products were identified as OH, NH, ClO, and other free radicals. From a detailed analysis of the temporal behavior of these emission bands, a decomposition mechanism via high-temperature oxidation pathways was inferred. The first stage of pyrolysis occurred at the crystal surface and, simultaneously, AP dissociated to form gaseous ammonia and perchloric acid. Experimental results revealed that the further decomposition of perchloric acid should be a three-body dissociation, i.e., $\text{HClO}_4 \rightarrow \text{OH} + \text{ClO} + \text{O}_2$.

Nanosecond and picosecond duration laser pulses were used to thermally shock AP crystals and study their response to rapid heating, simulating conditions that might occur in a rocket engine [415]. AP decomposition products were analyzed by XPS. Decomposition was initiated amid complex mechanical deformation and micro-cracking processes at the laser impact site but did not propagate at atmospheric pressure. Optical microscopy, SEM, and atomic force microscopy were used to examine the laser-damaged zones and revealed a micro-structure of ultra-fine cracks. It could be seen that despite the very short heating duration, some of the orthorhombic-cubic phase transitions had already occurred.

One advantage of laser pyrolysis is that the beam can be focused through the window in a high-pressure bomb and the reactions on the surface of the AP sample can be studied at very high pressures [416, 417]. The measurement of chemical and physical processes was demonstrated for AP decomposition at static high pressures (up to 2.0 GPa) and with pulsed-laser heating ($3\text{--}22 \text{ J cm}^{-2}$). Time-resolved UV-Vis absorption spectra collected during and after laser-pulse heating revealed the global reactions during ignition and combustion. The time evolution of the absorption $A(t)$ was used to model the global reaction kinetics. The dependence of $A(t)$ on pressure and laser fluence was consistent with a two-phase reaction. This reaction consists of initiation from hot spots and diffusion-limited reaction growth. A change in the contribution of initiation relative to growth in the overall reaction was observed between 1.3 and 1.6 GPa and was ascribed to structural changes in AP. Lasers can also be used for ignition studies of AP/aluminum mixtures [418].

4.3.4.3 T-Jump Pyrolysis Studies of AP With Electric Heaters

An AP sample was confined in a hypodermic needle capillary tube closed on one end with the other end feeding directly into the ionization chamber of a mass spectrometer [354]. When evacuating and heating the sample holder, vaporization started at

393 K (120 °C) and all AP had sublimed by the time the sample reached 473 K (200 °C). The undissociated parent ion $\text{NH}_4\text{ClO}_4^+$ could not be detected, indicating that the first step in AP decomposition is a proton transfer.

The major products of natural and isotopically labeled AP pyrolysis at low temperature at 10^{-3} mm Hg were analyzed in a constant-volume system connected by a molecular leak to a TOF mass spectrometer, which operated at an ionizing voltage of 70 eV [419]. NH_3 and HClO_4 did not evaporate directly into the ion beam but were eliminated by recombination on cold glass surfaces. $^{14}\text{NH}_4\text{ClO}_4$ decomposed at 503 K (230 °C) and produced products with masses 14–74. Parent peaks were at masses of 18, 28, 32, 36, 44, 70, 72, and 74, thus corresponding to H_2O , N_2O , Cl_2 , O_2 , HCl , and N_2 . Nearly all the NO produced came from N_2O . Not all of the N_2 came from N_2O .

Isotope labeling can help to identify the rate-determining steps in a sequence of decomposition reactions. The thermal decomposition products of $^{14}\text{NH}_4\text{ClO}_4$, $^{15}\text{NH}_4\text{ClO}_4$, and deuterated AP were analyzed by mass spectrometer [420]. By investigating the decomposition at approximately 10^{-4} mm Hg and also at 10^{-7} mm Hg in the mass spectrometer inlet system, it was possible to clarify some of the previously conflicting data. This investigation has shown that NH_4ClO_4 decomposes into O_2 , Cl_2 , and N_2O in the molar ratio of 3:2:2 at <573 K (<300 °C). Perchloric acid was not detected. The activation energies for the formation of O_2 and Cl_2 were the same (117 kJ/mol = 28 kcal/mol). This agrees quite well with those calculated in conventional constant-volume experiments. The ratio of O_2 : N_2O : Cl_2 in the decomposition products at 473–503 K (200–230 °C) was 3:2:2, which matches a stoichiometry similar to

A Knudsen-cell mass-spectrometric method yielded reproducible results only after the AP had been pre-dried under vacuum at 473 K (200 °C) for 48 hours [421]. Ion intensity was measured from 413 to 523 K (140 to 250 °C). Activation energies were derived from the slope of $\log IT/\sigma$ versus $1/T$ plots where I is the peak height of the ion, T is the crucible temperature in kelvin, and σ is the ionization cross-section of the specific ion analyzed. It is strange that this method did not show any perchloric acid. It is suspected that HClO_4 decomposed before it could be analyzed. Three energy steps were determined for the decomposition mechanisms of AP in the temperature range 418 K to 525 K. The activation energies obtained from the slopes of observed ion intensities versus cell temperatures for each of the three steps were 22.2 ± 1.1 kcal/mol, 29.9 ± 1.5 kcal/mol, and 44.0 ± 2.2 kcal/mol.

A sample of AP was deposited on a 0.04-mm tungsten filament and heated rapidly by discharging a capacitor through the filament, close to the inlet of a time-of-flight mass spectrometer [422]. Similar TOF mass spectrometer experiments were repeated with AP samples with or without the addition of 4% Fe_2O_3 as a catalyst. The sample was heated to 673 K under a partial vacuum of 10–200 mm Hg [423].

The pyrolysis products of AP were analyzed by TOF mass spectrometry [424]. The primary products of the breakdown reaction in the temperature range studied were ammonia and perchloric acid. The peaks at $m/e = 35, 51, 67, 83$, and 100 correspond to Cl, ClO, ClO₂, ClO₃, and HClO₄ [425]. Because ClO₂ is paramagnetic, it can also be analyzed by the intensity of its ESR signal after freezing out the condensables on an LN₂-cooled cold finger. The ratio of ClO₂/AP is an indicator of the degree of conversion and can be plotted as a function of time, resulting in S-shaped curves. The addition of various copper compounds acting as catalysts cause a shift of these conversion curves to lower temperatures. The concentration and the ratio of NH₃ to HClO₄ in the gas phase were close to what one would expect from a dissociation equilibrium. This is also viewed as a supporting argument for the proton transfer mechanism of AP decomposition.

In spite of the fact that the pyrolysis of AP has been exhaustively studied, two fairly important questions with respect to the decomposition process still remain: What are the exothermic reactions, if any, occurring in or on the surface of the solid and what are the rates and nature of gasification and subsequent gaseous reactions above the solid? A rapidly electrically heated stage holding AP crystals was connected to an evacuated chamber from which Knudsen flow carried decomposition products into a TOF mass spectrometer [373]. The results indicated the occurrence of an exothermic surface reaction with ClO₂ as a major product resulting from the pyrolysis of AP between 473 and 673 K (200 and 400 °C).

Measurements of the cold surface deposition rates from subliming AP as a function of sublimation temperature and the comparison of the mass spectra of subliming reagent grade AP with that of already sublimed AP reinforced the previously reported observations that decomposition competes with sublimation in the temperature range of 373 to 473 K (100 to 200 °C) [426]. Furthermore, the results also indicated that the sublimed AP is less stable than reagent grade AP.

A series of pyrolysis experiments of AP ranging from low-temperature solid-phase decomposition to high heating rate (10 °C/s) flash evaporation using skimming transient mass spectroscopy [427] was able to identify the gas-phase species. The aim of these experiments was to study the effects of gas-phase reactions and to determine the nature of AP pyrolysis at heating rates that are representative of actual propellant systems.

T-Jump/FTIR spectroscopy of pyrolysis that occurs in a thin layer of AP representative of a burning surface provides the sequence of appearance of the intermediate species and gaseous products [428]. A thin layer of AP was heated at 2000 °C/s to 713 K (440 °C) under 1.3 Mpa = 13 atm Ar. Some HClO₄, but no NH₃, escaped the reaction zone before significant heat was released. NH₃ was quickly oxidized to NO₂, N₂O, and H₂O. At least some of the N₂O may result from

As the decomposition rapidly accelerated and became strongly exothermic NO and H₂O were formed in large amounts and no more HClO₄ was evolved. These observations are consistent with the large influence of the reaction

in the overall rate. The acceleration of the process may result from growth in the HNO concentration. The final product concentrations qualitatively resemble the product profiles determined by microprobe-mass spectrometry of the AP flame.

Probing mass spectrometry (PMS) is a very useful method based on microprobe and molecular beam mass spectrometric probing for the study of solid propellant flame structures at high (10 atm) and low (< or = 1 atm) pressures. PMS has been utilized to study AP and ADN decomposition flames [429] using an installation for studying the thermal decomposition of AP at the high heating rate of the specimen up to 20–100 °/s and under conditions very similar to those present in the condensed phase in the vicinity of a burning surface. Flame structure studies of a sandwich based on AP allowed a confirmation of multi-zone structure and step-by-step mechanism of reactions in AP flame.

The fast thermolysis of AP and its decomposition mechanism under certain simulated conditions of combustion were studied by T-Jump/FTIR [430]. AP was flash-pyrolyzed under a nitrogen atmosphere at different pressures, with a heating rate of 1000 K · s⁻¹ at 874 and 1274 K. It was found that the main gaseous products of AP thermolysis were NO₂, N₂O, NO, HCl, and NClO. Interestingly, the N₂O/NO₂, NO/NO₂, and NO/NClO ratios increased with increasing temperature or pressure.

4.3.5 Other AP Decomposition Studies

A study of the decomposition behavior of pure single crystals of AP in a vacuum has been carried out. This took place during high heating rate decomposition at atmospheric pressure, and through self-deflagration in nitrogen atmospheres 2.06 < *p* < 34.4 Mpa (300 < *p* < 5000 psia) and deflagration in methane atmospheres 0.103 < *p* < 1.376 Mpa (15 < *p* < 200 psia). This helped to identify the rate-determining steps of the process [431].

The thermal decomposition of large single crystals of pure AP and AP doped with Ba²⁺ or SO₄²⁻ ions were investigated over the temperature range 493–563 K (220–290 °C) [432]. The study also included a comparison with compressed pellets of the pure powder and with small single crystals containing macroscopic flaws. The data revealed that the induction period is very complex and comprises a desorption step, a linear process, an exponential process, and the beginnings of an Avrami process. The latter three processes were identified with (1) the inward growth of rapidly formed surface nuclei, (2) branching of surface nuclei and (3) nucleation in the bulk crystal. Kinetic parameters were obtained for these three processes and

also for the growth of nuclei in the bulk crystal. This model matched the kinetic data over the entire range of degree of decomposition α (0 to 1), or $1 \times 10^{-5} < \alpha < 1$ if the desorption step is not included.

4.4 Ammonium Perchlorate Autoignition Temperature and Ignition Delay

Above a certain temperature, the rate of decomposition of AP becomes so fast that a runaway condition leads to autoignition and the production of flames. This event is also called [thermal explosion], depending on how vigorous the reaction is. The reaction may be powerful enough to destroy the sample holder or even the apparatus and its onset is dependent on the sample size. The time delay between arriving at the isothermal hold and the start of flames is often measured; it can be shown that it obeys an Arrhenius-type relationship if its logarithm is plotted against the reciprocal absolute temperature. Contaminants or catalysts will shorten the delay time and lower the activation energy. The time spent in transit from room temperature to the test temperature is usually ignored and is kept as short as possible.

Table 11 is a summary of autoignition temperatures reported by various sources in the literature. This table contains only data for pure AP. A similar table for AP with various additives is provided in Table 17, Section 4.7. The autoignition temperature depends on the gas and the pressure in the surrounding atmosphere.

The ignition delay time for AP heated to and kept at 753 K (480 °C) was ~90 s.

Table 11: Autoignition temperatures and activation energy of pure AP.

Author(s)	Year	Minimum autoignition temperature		Activation energy		Atmosphere	Pressure mm Hg
		K	°C	kJ/mol	kcal/mol		
Galwey and Jacobs [433]	1960	700	427	173.6	41.5	air	760
Osada and Sakamoto [357]	1966	<723	<450	284	68		
		>723	>450	96.2	23		

4.5 Ammonium Perchlorate Decomposition at Elevated Pressures

The majority of laboratory experiments on the decomposition of AP have been conducted at atmospheric pressure. However, this is not the pressure condition under which AP is actually used in rocket motors. There is a lot of academic discussion about AP decomposition mechanisms and the effect of various additives but very little information about how these mechanisms differ when they take place at elevated pressures.

The ignition delay of AP was determined in an electric furnace by measuring the time lag [434, 435]. The ignition delay for AP doped with Cr_2O_3 at 613 K (340 °C) was 135–140 s at 10^{-3} mmHg, whereas it was 56–81 s in the air at atmospheric pressure. The duration of preheating AP adversely affected the delay. The increase in particle size of AP was inversely proportional to the ignition delay. With large surface areas, the evaporation of HClO_4 was significant compared with the sublimation of crystals with small surface areas where evaporation is the rate-determining factor.

The linear pyrolysis rate of AP between 623 and 973 K (350 and 700 °C) at pressures between 101 kPa and 2.62 Mpa (1 and 26 atm) was measured in an apparatus where the substance to be tested is heated using a metal tape energized by a high-current-density and low-voltage transformer in an inert atmosphere within a pressure bomb equipped with an observation port [436]. The results of experimental measurements of the velocity of AP pyrolysis were then curve-fitted for data interpretation. It was shown that there are two pyrolytic domains. The first involves a process of pure pyrolysis and the second relates to the superposition of surface and exothermic reactions. An exothermic reaction took place in the higher temperature (pre-combustion) domain of pyrolysis, presumably similar to that which occurs during combustion. There was no sign of that heat release in the lower temperature region. The heat release began at temperatures in the transition zone between the two domains.

AP decomposition in a closed bomb ceased after the pressure of decomposition products had reached a limiting pressure [362, 437]. The limiting pressures were 147 kPa (1100 mmHg) at 403 K (130 °C), 200 kPa (1500 mmHg) at 423 K (150 °C), and 293 kPa (2200 mmHg) at 443 K (170 °C). Decomposition resumed immediately after the gas was vented and without an induction period. The mechanisms of AP and alkali metal or alkaline earth metal perchlorate decomposition are quite different. They depend on the strength of the base from which the salts are derived.

Extending decomposition studies of AP to extremely high pressures required a special anvil press with a cube-shaped pyrophyllite sample holder and tungsten carbide pistons. The pre-explosion rates of decomposition of AP and an AP-based propellant between 539 and 610 K (266 and 337 °C) were measured at 1.5, 2.5, and 5 Gpa (15, 25, and 50 kbar) [157]. The data were fitted to a first-order rate equation. Arrhenius plots of reaction-rate constants at different decomposition temperatures allowed the calculation of activation energies. For AP, the energies ranged from 169 kJ/mol (40.4 kcal/mol) at 1.5 Gpa to 239 kJ/mol (57.2 kcal/mol) at 5 Gpa. Activation energies for the AP propellant were calculated to be 127 kJ/mol (30.3 kcal/mol) at 1.5 Gpa and 203 kJ/mol (48.5 kcal/mol) at 5 Gpa. At high heating rates, decompositions of AP were explosive.

The thermal decomposition of AP in different gaseous atmospheres was investigated using DTA at pressures up to 5.15 Mpa (51 atm) [438]. It was found that the rates of the first and second stage of AP decomposition in an atmosphere of oxygen or nitrogen increases with pressure. Platinum, which may be used as a sample holder material or in thermocouples, has a catalytic effect on the HTD of AP. The heat of reaction of the

HTD of AP in a platinum cell was calculated from the peak temperatures of DTA curves at various pressures and found to be 326 kJ/mol (77.9 kcal/mol). The activation energy of AP sublimation in helium at 101 kPa (1 atm) is 96–105 kJ/mol (23–25 kcal/mol). The activation energy of the HTD in the platinum cell at various pressures of helium is very similar to that number.

The kinetics of the thermal decomposition of AP at high pressure were investigated by pressure differential thermal analysis (PDTA) [439]. It was found that the peak temperature of HTD moves up. In contrast, LTD on DTA curves of AP moves down with increasing pressure. The apparent activation energy E_{act} for the HTD increased but no changes in the kinetic parameters at LTD occurred as the pressure was raised. The results fit into a model for the mechanism and the rate-controlling process in AP decomposition [439].

4.5.1 Effects of Water on AP Decomposition

Although AP is not very hygroscopic (not nearly as bad as AN or ADN), its various properties are strongly affected by moisture. Water inclusions may become trapped in the crystals during manufacturing and recrystallization processes. Moisture may leak into storage containers during transportation and storage. Propellant processing is not always done in climate-controlled rooms. Many studies on the thermal decomposition and strand burning rates of AP were done without even the slightest effort to measure the water content of chemicals or control humidity in the test chamber. These studies suffer from a lack of reproducibility, and moisture is one of the likely causes for this problem.

The rate of thermal decomposition of AP is affected by moisture [348]. Cleaved single crystals with well-developed rhombic faces were mounted in a climate-controlled chamber under a microscope. These were photographed periodically during the experiment to follow the changes taking place throughout the slow thermal decomposition at 503 K (230 °C) [440, 441]. The air purging through the chamber was saturated to known levels of R.H. by passing it through dilute sulfuric acid in a hygrometer with specific water partial pressures. AP thermal decomposition below the phase transition temperature initially formed cigar-shaped nuclei. The number of nuclei was very small and depended on the purity and the history of the crystal. It remained constant while the decomposition was in progress and the dark zones grew until they overlapped. The results revealed that the water vapor primarily affects the rate of growth of the nucleation. The change of the nucleus growth rate with water vapor concentration is complex. At first, it decreased to a minimum at 15 g H₂O/m³, then reached a maximum and finally declined again. The effect of water vapor pressure on the growth rate of nuclei during thermal decomposition of AP revealed that the rate of nuclei formation is not affected by water vapor concentration. However, the nucleus growth rate was affected by changes in water vapor concentration. At the same time, the character of anisotropy of the nucleus development remained unaffected. Simultaneous changes

occurred in the growth rate of nuclei, both in the direction parallel to the principal axis of symmetry and perpendicular to it. Changes in nucleus growth rate occurred in sync with the changes in the total rate of thermal decomposition. This process was determined gravimetrically. Results were similar to results from experiments on dehydration of crystal hydrates.

In addition to the water carried in with the purge gas, some water is formed as the result of progressing decomposition of AP and may remain trapped in the crystal. The presence of water may enhance the proton exchange between decomposing AP and the ammonia and perchloric acid formed in its dissociation that remains adsorbed to the crystal instead of desorbing. Enhanced proton exchange accelerates the rate of decomposition. Perchloric acid also forms a hydrate that is more stable than the acid itself. Similar tests were performed with ammonia instead of water vapor in the purge gas.

Gas-phase reactions were simulated by computational chemistry methods at various levels of complexity using a generalized gradient approximation with a plane-wave DFT [442–444]. This was conducted in an effort to explain how water affects proton transfer on the surface and in solid AP. This method allowed exploration of the dissociation mechanism and the role that water molecules play in the surface decomposition process compared to those in the gas phase and in solution. For reactions inside or on the solid phase, a Vienna *ab-initio* Simulation Package was used to evaluate the total energies of periodically repeating geometries based on DFT with a pseudo-potential approximation. The energy-distance profile for water molecule(s) approaching or leaving the AP crystal surface was displayed graphically to illustrate the affinity of AP crystals for water. The predicted AP sublimation rate constants were calculated for different amounts of water in the vapor space. Calculations revealed that water molecules can readily desorb from the surface. The desorption energies of $(\text{H}_2\text{O})_1$, $(\text{H}_2\text{O})_2$, and $(\text{H}_2\text{O})_3$ clusters from the surface were 5.2, 12.8, and 9.5 kcal/mol, respectively. These results, together with the fact that H_2O desorbs readily from the AP surface with relatively low energies, suggest that the formation of a solution layer on a decomposing AP surface is not likely at high temperatures where AP sublimates. Water molecules do not affect the proton transfer process between $\text{NH}_4^+/\text{ClO}_4^-$ ion pair on the surface but they can significantly reduce the sublimation energy of AP by co-desorbing with the $\text{NH}_4^+/\text{ClO}_4^-$ ion pair. The sublimation energies of AP with $n\text{H}_2\text{O}$ ($n = 0, 1, 2, 3$) were predicted to be 117.5, 89.5, 77.8, and 59.4 kJ/mol (28.1, 21.4, 18.6, and 14.2 kcal/mol), respectively (see [445]).

The hygroscopicity and moisture sensitivity of the thermal decomposition of fresh and irradiated AP is different [446].

4.5.2 The Effect of Confinement and Pressure on AP Decomposition

The thermal decomposition of AP has been extensively studied in the past. Nevertheless, the various results published illustrate conflicting findings. On the one hand,

significant differences regarding the influence of different parameters on the decomposition can be seen. On the other hand, a lack of useful quantitative laws to predict the thermal behavior of this crystal under a range of operating conditions (temperature, duration of exposure, type of confinement) has been reported.

Kinetic curves were measured for the thermal decomposition of AP at 503 and 533 K (230 and 260 °C) [447]. An inert gas pressure of 10.1 Mpa (100 atm) failed to alter the kinetics of this reaction.

The course of AP decomposition proceeds through different paths if the decomposition products are trapped and in contact with the crystal surface. The same occurs if the decomposition products are carried away by vacuum or a purge gas [399, 401, 448].

In addition to the effect of confinement, the type of purge gas may also have an affect on the rate of decomposition of AP. It was observed that AP decomposition under nitrogen proceeded more slowly than under air [449]. Nitrogen is a decomposition product of AP and its presence may retard the decomposition by the law of mass action (but only if this is a reversible equilibrium reaction!).

4.5.3 The Effect of Thermal Pre-Treatment (Aging) on AP Decomposition

The effects of accelerated aging at 348 K (75 °C) on the thermal decomposition of AP were studied using DSC, TGA/DTG, and FTIR [450]. DSC thermogram of fresh AP showed the endothermic peak to be 520 K (246.9 °C), which was attributed to the phase transition of AP from orthorhombic to cubic form and two exothermic peaks, the first at 561.6 K (288.5 °C) (weak) and the second at 697 K (423.9 °C) (sharp). This was caused by the decomposition of AP. Samples were taken after 80, 120, and 140 days of aging. These were analyzed using DSC and FTIR and compared to the fresh sample. After 120 days of aging, the DSC thermogram showed two distinguished endothermic peaks at 595.8 K (322.7 °C) and at 704.3 K (431.2 °C), which was attributed to the decomposition of AP in two stages. Also, FTIR spectra showed a new peak at wave number 800 cm^{-1} , which was assigned to chlorate ions. The activation energies of aged AP decomposition calculated from TG/DTG isothermal data and a first-order rate equation method is summarized in Table 12

Activation energy goes through a minimum of 40 to 80 days of aging. Any samples exposed for >120 days were severely decomposed and the E_a numbers were unreliable.

In another aging test series, AP samples with four different particle sizes were aged, i.e., subjected to a thermal stress test in a closed sample holder consisting of an isothermal hold for ten minutes at 298 K (25 °C), a ramp at 10 °C/min. to 498 K (225 °C), and isotherm holds at 498 K (225 °C) for three hours [449]. To determine the fraction of unreacted product remaining following experiments in **closed** cells, the residues of AP were collected and subjected to thermal decomposition via TGA **open** cell for two hours at 498 K (225 °C). The weight loss rate was recorded. The decomposition topographic phenomena were illustrated by a series of very good SEM images which showed the evolution of porosity at different stages of the decomposition process.

Table 12: Activation energies of aged AP decomposition.

Aging duration, <i>d</i> , at 348 K (75 °C)	Activation energy, <i>E_a</i>	
	kJ/mol	kcal/mol
Zero	69.9	16.708
20	52.7	12.6
40	30.6	7.32
80	29.7	7.1
120	90.7	21.68
140	54.7	13.085

4.6 Kinetics of Ammonium Perchlorate Thermal Decomposition

The stoichiometry of AP decomposition depends on the rate of heating, the operating pressure, and the presence or absence of catalysts. Several stoichiometries were already presented in Section 4.3.1. A general equation can be written as

Authors of various comprehensive studies on the thermal decomposition of AP considered the following four possible pathways:

1. An electron transfer process from the perchlorate anion to the ammonium cation;
2. A proton transfer reaction from the cation to the anion (similar to the decomposition of all ammonium salts), accompanied by the formation of perchloric acid and ammonia;
3. The thermal breakdown of the perchlorate anion breaking a Cl—O bond similar to the thermal decomposition of perchlorates of alkaline metals; and/or
4. Formation of NO_2ClO_4 as an intermediate.

Before one can study the kinetics of AP decomposition, one must have a complete understanding of the dynamics of AP sublimation. Therefore, several studies were conducted to measure the sublimation vapor pressure of AP below the onset of thermal decomposition (see Section 3.3).

A transition-state decomposition rate theory for intermosaic orthorhombic AP decomposition looked at the electron exchange in adjacent NH_4^+ and ClO_4^- ions [451]. This theory was based on observations and measurements by Bircumshaw and Newman [348, 349]. They had observed that slow decomposition at 503 K (230 °C) proceeds by the formation of opaque spots (nuclei) on the crystal surface. Schultz and Dekker [451] developed a single consistent treatment of the kinetic data in terms of the linear rate of progression of the interface between the partially decomposed and undecomposed crystalline material.

Over the past century, many investigations have been performed to study the decomposition kinetics of AP. The principal results of these studies have shown that AP decomposes in two stages: At low temperatures ($T < 573 \text{ K} = T < 300^\circ \text{C}$) 30% of the AP is decomposed and the rest of the material is left as a structured, porous residue, and at temperatures above 623 K (350 °C) this residue is subjected to a second stage, exothermic decomposition until all the material is consumed. The justification most frequently used for studying the decomposition of AP is that the behavior of AP in the combustion zone of composite propellants greatly influences the overall combustion and the burning rate of the propellant. Because isothermal decomposition tests possess the desirable attribute of controlling experimental variables with relative ease and are less time-consuming, many studies of the kinetics of AP decomposition have been performed and the results extrapolated to speculations about the burning rate. The question of the relevance of these decomposition results in relation to the behavior of AP particles in a burning propellant has been the subject of extended discussions. A thesis by Siegmund [452] provides a good introduction to this topic due to how it contains an excellent summary of the literature on AP decomposition up to 1969.

The precise nature of the reaction mechanism was a subject of discussion for a long time. Thus, some authors expressed the opinion that the limiting stage in the thermal decomposition of AP is the transfer of an electron from the ClO_4^- ion to the NH_4^+ ion. An investigation of the catalytic activity of the oxides of metals of variable valence in the thermal decomposition of NH_4ClO_4 has revealed the existence of a relationship between the electrical properties of the oxides and their catalytic activity. It has also served to confirm electron transfer assumptions. Other investigators arrived at the conclusion that the stage controlling the reaction rate involves the transfer of a proton from the ammonium ion to the ClO_4^- ion. It was also suggested that both mechanisms co-exist: at relatively low temperatures electron transfer is the dominant mechanism, and in the high-temperature region proton transfer is the dominant mechanism. Other theories of the mechanism of perchlorate and nitrate decomposition reactions have been proposed but they have been less widely accepted than the aforementioned mechanisms. The extensive experimental data now makes it possible to construct a general picture of the decomposition of inorganic nitrates and perchlorates [453]. Particularly noteworthy is the fact that ammonium salts are more easily decomposed than salts of the alkali and alkali earth metals. This is typical, not only of perchlorates and nitrates but also of permanganates, bichromates, carbonates, etc. The basic difference between the NH_4^+ ion and the metal ions is its ability to transfer a proton to an anion. The principal objection to proton transfer is that, for AP, the heat of sublimation is approximately 251 kJ/mol (60 kcal/mol), i.e., much higher than the observed activation energy. Owing to the high values of the N—H or Cl—O bond energies, it is difficult to find an energetically favorable elementary event without assuming yet unseen intermediate states. The idea of electron transfer from anion to cation through the forbidden band, though widely held, has not yet been experimentally confirmed. The direct spectral investigation of AP crystals has shown that the

forbidden gap is greater than 4 eV, which exceeds the observed activation energy of the reaction. In order to explain the relatively low values of the activation energy of decomposition of NH_4ClO_4 (125 kJ/mol = 30 kcal/mol) it may be necessary to introduce the idea of electron transfer, although not to the conduction band but to various kinds of electron traps (see [454–458] also).

4.6.1 Experiments in Support of Electron Transfer Processes

The thermal decomposition of AP in vacuo and under small initial pressures of nitrogen, to suppress sublimation, was investigated in the temperature ranges 493 to 553 K (220 to 280 °C) and 653 to 723 K (380 to 450 °C) [348]. In the low-temperature range, only 30% decomposition occurred and much of the residue consisted of AP. In vacuo, sublimation occurred all of the time, including once decomposition had ceased. This indicated that the reaction did not take place in the vapor phase. The sublimed material and the ‘residue’ were analyzed. Surprisingly, it was found that the residue which was porous in texture (the decomposition had occurred throughout the crystal) could be ‘rejuvenated’ via exposure to a solvent vapor and the decomposition could begin anew. The crystals undergo a transformation at 513 K (240 °C) from orthorhombic to cubic crystal structures. During the AP LTD process at temperatures ranging from about 473 to 553 K (200 to 280 °C), a time delay of a few minutes to more than half an hour was observed. Such time delays before AP gaseous products emissions are called induction periods. Once started, AP LTD gassing rate was much faster at 503 K (230 °C) than at 518 K (245 °C). Since the AP phase change temperature is 513 K (240 °C), decomposition kinetics close to that temperature was faster in the lower-temperature stable orthorhombic crystal phase than in the upper-temperature stable cubic phase. Within decomposing coarse AP particles, one can observe microscopic cloudy particles that could coalesce into larger, but still quite small, reaction centers. Holes in coarse AP particles started to appear at subsurface reaction centers that were observed as cloudy spots under microscope observation. Such holes or pores were sources of AP decomposition products. Additives from both co-crystallized and external vapor exposures changed AP LTD rates or induction periods. The addition of impurities, which might be intermediate decomposition products, and the addition of metal oxides affected the rate of decomposition. The energy of activation of the thermal decomposition over the temperature range 488 to 548 K (215 to 275 °C) was 116 kJ/mol (27.8 kcal/mol) for the orthorhombic form and 79 kJ/mol (18.9 kcal/mol) for the cubic form [349]. The rate of decomposition was found to increase to a maximum with decreasing particle size and then to decrease again. An electron transfer mechanism was proposed, which explains some of the observed decomposition results.

In the early rocket age, there were some authors [360, 459] who believed that thermal decomposition, at least under some special conditions (e.g., low temperature and in the presence of a catalyst), occurred due to electron transfer from perchlorate ion to ammonium ion. This provided fodder for many lengthy disputes and the problem of

the real mechanism of AP thermal decomposition was not quite solved for many years. It took several decades to sort out the experimental evidence and arrive at a conclusive agreement. A better understanding of AP decomposition was only possible after the decomposition of HClO_4 , which was formed following the thorough investigation of the decomposition of AP.

It was argued that because manganese salts, manganese dioxide [460], and potassium permanganate catalyze the AP decomposition at low temperatures, it will point to an electron-transfer mechanism because the manganese ion can assume many different states of oxidation. Others suggested that p-type semiconductor metal oxides (CuO or Cr_2O_3) enhance catalytic decomposition of AP on account of their increased electron-hole density [461, 462]. The doping of semiconductor oxides supported this theory. In semiconductor oxides, electron and electron defect concentrations can be increased by incorporating ions of different valencies. Catalytic effects observed with CdO or ZnO must be explained using different mechanisms, however.

Another reaction mechanism proposed by [459] for the uncatalyzed decomposition involves the adsorbed dissociation products NH_3 and HClO_4 , self-protonation of HClO_4 to yield the intermediate ClO_3^+ , and oxidation of NH_3 by ClO_3^+ . The reaction mechanism proposed for the catalyzed decomposition involved the formation of the free radicals $\cdot\text{NH}_4$ and $\cdot\text{ClO}_4$, decomposition of the radicals to NH_3 and chlorine oxides, and subsequent oxidation of NH_3 . The experiments in the temperature range from 523 to 598 K (250 °C to 325 °C) also studied the effect of copper chromite and atmosphere composition on the rate of AP decomposition.

If the AP decomposition proceeds as an electron transfer process, then the reaction should be affected by conducting it in an electrostatic field. This is because electrically charged particles will travel between the electrodes. A novel method for detecting the charge-carrying species in decomposing inorganic salts was applied to AP decomposition [463]. It was observed that the charge-carrying species at two different temperatures (423 and 503 K = 150 and 230 °C) are oppositely charged, i.e., they are negatively charged (ClO_4^- ions) at 423 K and positively charged (NH_4^+) at 503 K.

The effect of aliovalent ion substitution on the decomposition rates of AP has been interpreted as supporting an electron transfer mechanism. In this case, the rate of isothermal decomposition of cubic AP as a function of the concentration of barium dopant concentration was measured by using TGA within the temperature range of 530 to 550 K [464]. The rate of decomposition first passed through a minimum and then a maximum. The dopant showed opposite effects in the two temperature ranges. The decomposition kinetics of both pure and doped AP were best described by a first-order rate law equation with an activation energy of ~138 kJ/mol.

It was proposed that a complex can be formed between a metal ion perchlorate and an $\text{NH}_4\cdot$ radical, which stabilizes the electron transfer process [465].

Most experimenters will hesitate to place a sample of AP inside an expensive scanning electron microscope and heat it to decomposition to observe topographical

changes. However, when this was attempted, it was noted that decomposing AP emits exo-electrons [466]. The rate of exo-electron emission was measured at constant temperatures. Different emission peaks were obtained with isothermal samples at low and high temperatures and in transient temperature experiments with different heating rates. SEM images of the surface of crystals at different stages of decomposition provided additional information on the decomposition phenomena.

4.6.2 Experiments in Support of Proton Transfer Processes

Galwey and Jacobs [467] concluded from their HTD data that the rate-controlling step was either due to the evaporation of an ion pair ($\text{NH}_4^+ + \text{ClO}_4^-$) followed by gas-phase reaction or because of proton transfer on the surface, which produced ammonia and perchloric acid. Since they assumed that the activation energies for sublimation and for the HTD were different, it was inferred that the HTD takes place via proton transfer.

The thermal decomposition of AP at low temperatures shows several unusual characteristics. The most striking of these is that at low temperatures it decomposes only to the extent of about 20 to 30%, leaving a residue that is chemically identical to the original salt [468]. The experimental results for the rate of decomposition of whole crystals, powder, and pellets could be well-fitted by a kinetic equation. This is in accordance with a detailed model for decomposing salt. It was possible to account in terms of this model (which involved the decomposition of intergranular material only) for the observed dependence of the activation energy on the extent of cold-working to which the solid is subjected, leaving residual strain in the crystal lattice. The cessation of reaction after about 30% conversion was attributed to the presumed ease of ammonia desorption relative to that of perchloric acid, which builds up on the surface. Other authors have suggested that the build-up of HClO_4 on the surface leads to HClO_4 decomposition on the surface

followed by a reaction with ammonia

Early experimenters revealed that the activation energy of AP thermal decomposition was practically the same at both low and high temperatures [469]. This mechanism involves a proton transfer from NH_4^+ to ClO_4^- ions on the AP surface as the initial step. Subsequent steps depend on the temperature and the ambient pressure and may involve one or more of: desorption, heterogeneous decomposition on the surface of AP, and homogeneous decomposition in the gas phase. The main nitrogen-containing products of decomposition are N_2O and HNO_3 at low temperatures and NO at high temperatures. IR and mass spectrometric investigations have not been able to detect a molecular NH_4ClO_4 species in the gas phase above decomposing AP. The rate of

decomposition is faster than the rate of sublimation. Both sublimation and thermal decomposition proceed by proton transfer. Measurements of the weight loss or pressure increase at low temperatures revealed that the rates were independent of the experimental method used (with or without removal of the decomposition products). Gas-phase reactions are not rate-determining.

The thermal decomposition of AP starts not over the whole crystal volume or on the whole surface at the same time but in specific nucleation sites near the outer and inner surfaces of a crystal. Having started at these active centers of a crystal, the reaction propagates near the place where it has already started and spreads. That is, the formation and growth of reaction nuclei occur. Reaction nuclei grow and merge with each other, thus forming the reaction region. The propagation is well seen with a microscope. Some sites on the crystals are preferred sites for the onset of decomposition (nucleation sites). These sites are linked to impurities or crystal defects and one would expect to obtain different results for highly purified AP. Based on weight-loss measurements, the activation energy of AP decomposition was the same in the low- and in the high-temperature regime, ~ 125 kJ/mol (~ 30 kcal/mol) in either case. From these data, Jacobs [469] and Russell-Jones [470] concluded that AP thermal decomposition usually occurs by the second of the aforementioned mechanisms where ammonia and perchloric acid are the initial products of decomposition. A similar viewpoint was proposed by Markovitz and Boryta [109].

Kinetics of AP decomposition can be derived from experiments run under isothermal or isoconversional conditions. Another alternative is to allow the reaction to proceed under adiabatic conditions by compensating for heat losses to the environment. An adiabatic method for studying exothermic solid reactions has been developed at Stanford Research Institute (SRI) [471]. Adiabatic conditions can be maintained with this apparatus in samples of a few grams weight for rates of temperature rise from 2–150 °C/min. The adiabatic decomposition of AP has been studied in this apparatus in a temperature ranging between 513–598 K (240–325 °C). The slab-shaped sample was clamped between two heater plates and held in position by spring-loaded bolts. As the sample began to decompose, the temperature of the sample rose above that of the plates. Electrical power was then supplied to the heater plates, which was manually controlled using a variable transformer, at a rate sufficient to maintain a uniform temperature in the plates and sample. As the reaction rate increased, the rate of power supply was correspondingly increased. Under these conditions, the temperature of the sample increased at a rate that depended ideally only on the rate of decomposition. The temperature difference between the plate and sample was kept to less than 0.2 °C up to a rate of temperature rise of about 100 °C/min., the maximum rate at which it was possible to supply sufficient power to maintain isothermal conditions in the assembly. The apparent activation energy derived from an Arrhenius plot was 129.7 kJ/mol (31 kcal/mol). This was higher than activation energies for isothermal decomposition reported by others in existing

literature ($96.2 \text{ kJ/mol} = 23 \text{ kcal/mol}$; $113 \text{ kJ/mol} = 27 \text{ kcal/mol}$). The heat release was compared to that expected from the equation

and matched the predictions.

Other methods to study the decomposition of AP are either based on weight loss in a TGA apparatus or on pressure increase in a closed bomb. TGA measurements are complicated by the concurrent sublimation of the salt. Measurements of the sublimation rate have, therefore, been made over a wide temperature range and kinetic parameters both for sublimation and for thermal decomposition have been established [472]. The activation energy for the low-temperature thermal decomposition was measured as $111.4 \pm 3.64 \text{ kJ/mol}$ ($26.63 \pm 0.87 \text{ kcal/mol}$) from Avrami-Erofeev rate constants and $125.8 \pm 8.28 \text{ kJ/mol}$ ($30.08 \pm 1.98 \text{ kcal/mol}$) from induction periods. The activation energy for sublimation is $117.32 \pm 1.8 \text{ kJ/mol}$ ($28.04 \pm 0.43 \text{ kcal/mol}$) from contracting volume rate constants. It was not clear whether the activation energy for decomposition changes at the phase transition point. The least mean squares values were $141.88 \pm 6.86 \text{ kJ/mol}$ ($33.91 \pm 1.64 \text{ kcal/mol}$) below the transition point and $112.8 \pm 9.87 \text{ kJ/mol}$ ($26.97 \pm 2.36 \text{ kcal/mol}$) above the transition point. The catalytic effects of ammonia (negative) and of perchloric acid (positive) have led to the formulation of a unified mechanism for sublimation and decomposition, which involved proton transfer from NH_4^+ to ClO_4^- ions as the basic step.

While it is generally accepted that the principal initial step in the decomposition of AP is proton transfer, details of the subsequent reactions had not been resolved for several years after this mechanism was first proposed. Data on HClO_4 and ClO_2 flames, on the oxidation of NH_3 , on reactions of nitroxyl, and on the reactions of chlorine oxides published in the 1960s were used to deduce a detailed mechanism for the decomposition of AP [473]. While attention has been focused primarily on the so-called HTD, the basic mechanism is adaptable to a wide range of conditions: to the LTD, to combustion, to the catalyzed decomposition, and to decomposition in the presence of various reactive gases. The central point of the proposed theory is that in the decomposition of AP, NH_3 is oxidized principally by the ClO radical.

The initial step in the thermal decomposition of AP is a proton transfer, based on electrical conductivity measurements and solid-state electrolysis of AP single crystals [474].

Exposure to an ammonia-rich atmosphere allows ammonia molecules to be absorbed into AP crystals at interstitial sites. It has been proposed that these neutral ammonia molecules can form short-lived N_2H_7^+ complexes with the NH_4^+ ions allowing proton transfer between them, thereby enhancing the electrical conductivity considerably. To date, however, there has been no direct evidence of this proposed mechanism. There are only theoretical calculations of an anomalous charge transport mechanism in AP crystals in ammonia-rich atmospheres [174]. The charge-transport mechanism in solid AP crystals exposed to an ammonia-rich environment was studied using *ab ini-*

tio molecular dynamics [475]. In this paper, *ab initio* molecular dynamics techniques were employed to explore a proton transfer mechanism. Computed infrared spectra of the pure and ammonia-doped crystals showed a significant broadening of the NH stretch peak into a lower frequency region. This indicated, through an experimentally verifiable observable, the formation of hydrogen bonds between NH_3 and NH_4^+ units. Comparison of the diffusion constants of NH_4^+ in the pure and doped crystals produced a ratio that was comparable to the experimentally measured conductivity ratio. It clearly showed enhanced positive charge mobility. The possibility of an ammonia umbrella inversion following proton transfer from NH_4^+ and NH_3 adds to the flexibility of this process.

Many of the experimental and theoretical studies mentioned favor the proton transfer hypothesis. However, *ab initio* MD simulation calculations [174, 475] indicated no proton transfer in the ideal crystal.

4.6.3 Experiments in Support of Formation of Nitryl Perchlorate as an Intermediate

The low-temperature (<570K) decomposition is incomplete (approximately 30%), yielding a residual solid with a composition and crystal structure very similar to those of the original reactant. The formation of NO_2ClO_4 as an intermediate during the LTD of AP has been postulated [476–478]. Analytical evidence has been obtained with the finding that an oxidized nitrogenous species is formed during the low-temperature thermal decomposition (ca. 500 K) of AP. The estimated reaction rate of NO_2ClO_4 closely accounts for the observed rate of AP breakdown. Nitryl perchlorate was proposed as a reaction intermediate. This proposed mechanism is quite different from either the electron transfer or the proton transfer mechanisms.

It is interesting to note that nitryl perchlorate also has been patented as a burning-rate increasing additive for AP. However, attempts to introduce synthetic NO_2ClO_4 directly onto the AP reactant resulted in no marked acceleration of reaction. This observation was readily explained by the instability of the additive at the reaction temperature (giving it a lifetime of only 5 s) and its sensitivity to hydrolysis [479]. In addition, the reaction rate of AP prepared with a low water content was greater than that of salt recrystallized from water, which can be explained by a lessening of the extent of hydrolysis of NO_2ClO_4 .

4.6.4 Other AP Decomposition Experiments

Free-radical, thermal, and photolytic decomposition products of AP were compared to those of cyclic nitramines and ADN [480]. The kinetics of the thermal decomposition of AP at temperatures between 488 and 533 K (215 and 260 °C) was studied by measuring the sample mass loss as a function of time applying the isothermal thermogravimetric method [481]. From the temperature dependence of the maximum decomposition rate, two different decomposition stages, corresponding to two different structural phases of AP, were identified. For the first region (488–508 K = 215–235 °C),

corresponding to the orthorhombic phase, the mean value of the activation energy was 146.3 kJ/mol, and the pre-exponential factor was $3.43 \times 10^{14} \text{ min}^{-1}$. For the second region (513–533 K = 240–260 °C), corresponding to the cubic phase, a mean value of the activation energy of 153.3 kJ/mol and a pre-exponential factor of $4.11 \times 10^{14} \text{ min}^{-1}$ were obtained. In an earlier publication the same authors had cited $E_{\text{act}} = 134.5 \text{ kJ/mol}$ and a pre-exponential factor of $1.05 \times 10^{11} \text{ s}^{-1}$ for a temperature range of 513–523 K (240–250 °C).

A combination of TGA, DSC, MS, and FTIR simultaneous analysis was used to study the thermal decomposition of AP [406]. The MS-FTIR spectra showed that N_2O and NO_2 were the main gaseous products of the thermal decomposition of AP, and there was a competition between the formation reaction of N_2O and that of NO_2 during the process with an iso-concentration point of N_2O and NO_2 . The dependence of the activation energy calculated by an iso-conversional method on the degree of conversion indicated that the AP decomposition process can be divided into three stages. These are autocatalytic, low-temperature diffusion, and a high-temperature stable-phase reaction.

The kinetic parameters for rapid pyrolysis of AP were determined by TGA [482].

4.6.5 Isotope Effects on AP Decomposition

If proton transfer is a key step of AP decomposition, then replacing hydrogen with deuterium should have a measurable effect on decomposition kinetics. The thermal decomposition of NH_4ClO_4 and ND_4ClO_4 single crystals was measured by DTA, TGA, and SEM. The volatile products that evolved were analyzed using mass spectrometry in real time [483]. Exothermic decomposition of the deuterated sample was slower but the phase change occurred at the same temperature (513 K = 240 °C), as can be seen from the thermograms in Figure 22.

Contrary to reports from other investigators who stated that decomposition starts at edges and imperfections on the surface of crystals, it was observed that thermal decomposition of NH_4ClO_4 and ND_4ClO_4 always started in the bulk of the crystals. In both cases, decomposition stopped when the degree of conversion was about 30%. Porous products were produced which underwent the same phase transition as the parent single crystals. If pre-decomposed porous samples were temperature-cycled just above 513 K, but below the upper onset of exothermic decomposition, the phase changes of both deuterated and non-deuterated AP are reversible and occur at the same temperature (Figure 23).

Examining partially (30% mass loss) isothermally decomposed NH_4ClO_4 and ND_4ClO_4 under the SEM revealed that the pores of ND_4ClO_4 were smaller and the volume fraction of pores appeared to be lower than that of NH_4ClO_4 (Figure 24). These effects were interpreted as caused by proton transfer at the intersections of dislocations in the bulk of the crystals.

Figure 23: Linear heating and cooling of NH_4ClO_4 and ND_4ClO_4 without decomposition. (Reprinted and modified from [483], with permission from Elsevier; permission conveyed through RightsLink.)

Figure 24: Comparison of SEM images of porous NH_4ClO_4 (top) and ND_4ClO_4 (bottom) at three different magnifications. (Reprinted and modified from [483], with permission from Elsevier; permission conveyed through RightsLink.)

An examination of the thermal behavior of large single crystals of partly and completely deuterated AP by DSC, SEM, TGA, and QMS revealed that the rates of thermal decomposition depend on the degree of deuteration and decreased in the sequence $\text{N}[\text{H}/\text{D}]_4\text{ClO}_4 > \text{NH}_4\text{ClO}_4 > \text{ND}_4\text{ClO}_4$ [484].

4.6.6 The Effect of Perchloric Acid on AP Decomposition

4.6.6.1 Decomposition of Perchloric Acid

One of the many reactions taking place during the decomposition of AP is the decomposition of perchloric acid. One would not consider perchloric acid as an oxidizer in liquid bipropellant combinations or as a monopropellant. We presume the main reason why people investigate the decomposition of HClO_4 is the role it plays in the decomposition of AP [485]. Perchloric acid is so much less volatile than ammonia that it stays behind on the surface of decomposing AP crystals, is adsorbed onto the crystals, and strongly influences the decomposition processes taking place on the surface. The higher decomposition rate of HClO_4 in the presence of AP can be explained by the heterogenic nature of the process [486]. In these nuclei, the oxidation of AP occurs, as

does the formation of an additional amount of HClO_4 . This acid causes the formation of new reaction nuclei on the adjacent defects and so on.

One of the decomposition products of perchloric acid is OCIO . The rate of OCIO formation can be taken as an indication of the rate of AP decomposition. The presence of ClO_2 in the products was believed to have special importance for explaining the behavior of AP under heating. ClO_2 was thought to initiate the combustion process in perchlorate. It should also be noted that ClO_2 , which is a stable paramagnetic molecule, can be detected with the help of electron paramagnetic resonance among the products of low-temperature thermal decomposition of AP [487]. The rate of ClO_2 formation can be modified by heterogeneous catalysts, while the amount of ClO_2 formed during AP decomposition remains unchanged. The addition of homogeneous additives by cocrystallization into AP crystals, for example the incorporation of SO_4^{2-} ions, changes both the rate of ClO_2 formation and its yield.

The decomposition of perchloric acid may be catalyzed using the same substances that catalyze the decomposition of AP. As a matter of fact, if one can show a good correlation between the relative reactivity of a series of catalysts for the decomposition of AP and HClO_4 , this may be in support of theories that postulate HClO_4 decomposition as a rate-determining step in AP decomposition.

A close relation had been observed between the catalytic effect of the metal oxides on the decomposition of HClO_4 and the thermal stabilities of the corresponding perchlorates. Namely, that is, that the most active oxides produce the most unstable perchlorates. An attempt was made to compare the catalytic effect of the oxides on the decomposition of perchloric acid and on that of AP. Using the same catalyst in both cases, it was concluded that there is no direct correlation between the relative activity of the oxides in the two reactions.

The effect of chromium(III) oxide on the vapor-phase decomposition of perchloric acid was studied in a flow system [488]. Chromium oxide showed a catalytic effect even at 383 K (110 °C). It was observed that perchloric acid oxidized the chromium oxide, especially above 443 K (170°). As a result, the activity of the catalyst decreased with time. The rate of the catalytic decomposition was practically independent of the perchloric acid concentration. The activation energy was 129.7 kJ/mol (31 kcal/mol).

The vapor-phase decomposition of perchloric acid has been investigated for all the oxides previously studied in connection with the decomposition and combustion of AP [489]. The experiments were carried out in a flow system, using N_2 as carrier gas. The interaction between the catalysts and the substratum was studied using electric conductivity measurements, IR spectroscopy, and chemical and thermal analysis. The oxides catalyze the composition of perchloric acid in the temperature range between 403–673 K (130–400 °C), depending on the metal ion. For 0.5% to 8% conversion per minute, the catalytic decomposition followed first-order kinetics. An exception was chromium oxide, for which the reaction was found to be of zero order. The activation energies determined for the different catalysts ranged from 83.7 to 188 kJ/mol (20 to 45 kcal/mol).

A flow system with nitrogen as carrier gas was used to study the vapor phase decomposition of HClO_4 on propellant catalysts (CuCr_2O_4 , CuCrO_4 , and CuO and a Harshaw Cu-0202 catalyst) [490]. The most effective compound, CuCr_2O_4 , catalyzed the decomposition at $\sim 393\text{ K}$ ($\sim 120^\circ\text{C}$). The reaction equation was

CuO had some catalytic effect above 543 K (270°C), while CuCrO_4 decomposed HClO_4 only above 603 K (330°C). Different types of deactivating side reactions occurred between the catalysts and HClO_4 and were strongly temperature-dependent. The interaction between the catalysts and perchloric acid was studied by IR, kinetic, gravimetric, electric conductivity, chemical, and thermal analytical methods. IR spectroscopy revealed the formation of a surface perchlorate ion on all the catalysts. Simultaneously, oxidation of catalysts containing CuCr_2O_4 occurred. The extent of oxidation increased at higher temperatures when the surface ClO_4^- decomposed. The HClO_4 decomposition was first-order except on CuCrO_4 , where it was zeroth order. The activation energies were $71.1\text{--}175.7\text{ kJ/mol}$ ($17\text{--}42\text{ kcal/mol}$). The effects of the same catalysts on the $\text{NH}_3\text{--HClO}_4$ reaction at $573\text{--}673\text{ K}$ ($300\text{--}400^\circ\text{C}$) were also investigated with perchloric acid and ammonia at different temperatures.

A difference in the effects exerted by metal oxides under different experimental conditions can be attributed to the additional heat release due to the decomposition of perchloric acid on the catalyst. Thus, by comparing the activity for AP and HClO_4 decomposition, the following series of decreasing activity of catalysts for AP decomposition at $T = 360^\circ\text{C}$ was produced: $\text{Co}_2\text{O}_3 > \text{CuO} > \text{Fe}_2\text{O}_3 > \text{MnO}_2 > \text{CuCrO}_3 > \text{Al}_2\text{O}_3 > \text{SiO}_2$ and for catalyst of the decomposition of HClO_4 : $\text{Co}_2\text{O}_3 > \text{MnO}_2 > \text{CuO} > \text{Fe}_2\text{O}_3 > \text{CuCrO}_4 > \text{Al}_2\text{O}_3 > \text{SiO}_2$ [491] (see [492, 493] also).

4.6.6.2 The Decomposition of AP in the Presence of Excess Perchloric Acid

When 5% HClO_4 was added to AP, and the sample heated in a DTA, an exothermic reaction began at 413 K (140°C) and peaked at $\sim 468\text{ K}$ ($\sim 195^\circ\text{C}$), which was much lower than with pure AP. After the AP phase-transition there was a sharp exotherm peaking at 588 K (315°C) [263]. The addition of HClO_4 to AP produced some interesting DTA results. At a temperature slightly higher than its boiling point, there was an exotherm that would appear to be a heterogeneous reaction between gaseous HClO_4 and undissociated AP. A large exotherm occurs around 300°C , the temperature at which exotherms appear in transition metal and ClO_3^- catalyzed AP. Since this temperature is lower than the temperature at which homogeneous decomposition of HClO_4 would be significant, the reaction is most likely either the direct reaction of HClO_4 with AP or due to catalysis byproducts forming in the reaction occurring at 473 K (200°C). When the system is subject to pressure, the LTE disappeared (the higher pressure requires a higher temperature for HClO_4 to boil). However, the sample deflagrated at $\sim 593\text{ K}$ ($\sim 320^\circ\text{C}$), which is lower than the temperature at which pure AP deflagrates at 1.72 Mpa ($17\text{ atm} = 250\text{ psia}$). It appears that below $\sim 573\text{ K}$ ($\sim 300^\circ\text{C}$)

the direct reaction of HClO_4 with AP (both reactants in the condensed phase) is not particularly rapid.

It has been shown that the rate of nuclei formation and the rate of nuclei growth is proportional to the partial pressure of perchloric acid in the atmosphere above decomposing AP crystals at 503 K (230 °C) [425, 17]. Figure 25 illustrates the effect of excess perchloric acid partial pressure on the maximum number of nuclei per surface area of AP decomposition at 503 K (230 °C). Perchloric acid and ammonia counteract each other in this process. Ammonia has the opposite effect on nuclei growth.

Figure 25: Effect of perchloric acid partial pressure on (1) the rate dN/dt of nuclei formation and (2) the maximum number of nuclei per surface area during AP decomposition at 503 K. (Republished and modified from [17], with the permission of © 2006 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center).

Legend: Left ordinate scale: rate dN/dt of the number of nuclei formation; right ordinate scale: rate of nuclei formation per unit area.

Perchloric acid vapor flowing over decomposing AP in a TGA apparatus reduced the time lag and significantly increased the rate constant of the acceleration period of AP decomposition [494]. The activation energy and the extent of decomposition was hardly influenced. Microscopic examination revealed that the formation of nuclei was greatly enhanced by the presence of HClO_4 . TGA experiments of this type were conducted in the temperature range 473–513 K (200–240 °C), 533–573 K (260–300 °C), and >613 K (340 °C) [495]. At <513 K (<240 °C), the HClO_4 vapor significantly reduced the induction period but the activation energy (125 kJ/mol = 30 kcal/mol) remained unchanged. At higher temperatures, the HClO_4 vapor had a similar effect but the activation energy was 12–20 kJ/mol (3–5 kcal/mol) lower than in a baseline experiment under inert gas (nitrogen). Even at very low HClO_4 partial pressures and flow rates

(5×10^{-8} mol/min) the HClO_4 vapor exerted a clearly observable effect on the decomposition of orthorhombic AP. When the introduction of HClO_4 was delayed until after the normal time lag, only very slight or hardly any acceleration occurred. The extent of AP decomposition was hardly influenced by the presence of HClO_4 vapor. It was found that decomposition usually stopped at 25–28% conversion [496].

Excess perchloric acid accelerates the decomposition of AP, while excess free ammonia retards it. Bircumshaw and Newman [348, 349] have suggested that the formation of centers of decomposition on the AP crystal surface may be associated with the formation of adsorbed perchloric acid. The induction period is shortened by crystallizing an AP sample with 2% excess perchloric acid. Conversely, the induction period is lengthened by passing some ammonia over the salt.

4.6.6.3 The Effect of Excess Ammonia on AP Decomposition

AP recrystallized from a solution containing excess ammonia at pH 12 then washed and dried carefully was found to have fewer crystal defects than AP recrystallized from water, based on XRD examination [359]. If the crystals were pulverized extensively, the thermal stability of the NH_3 -doped crystals decreased. At all pressures, AP is more stable in an atmosphere containing NH_3 than under pure N_2 [263].

Excess perchloric acid and excess ammonia have exactly the opposite effects on the rate of decomposition of AP. Ammonia forms as the result of proton transfer during the first step of decomposition of AP in the condensed phase. Part of the ammonia remains adsorbed to the crystals and the rest is released into the gas phase. At very high pressures, both perchloric acid and ammonia cannot desorb. They will remain and react in the condensed phase. The rate of subsequent reactions depends on the rates of reaction of ammonia with oxidizers in the gas phase. If excess ammonia is provided during a laboratory experiment, the release of ammonia is retarded and more ammonia accumulates in the condensed phase.

Figure 26 shows the effect of the partial pressure of ammonia above decomposing AP crystals at 503 K (230 °C) on the maximum number of nuclei per surface area (n_{max}).

Both the nucleus formation rate and the maximum number of nuclei per surface area decrease when ammonia partial pressure is increased. It is assumed that the reaction nuclei forms as a result of AP dissociation. Indeed, the number of nuclei rises when perchloric acid partial pressure is increased in the atmosphere above the crystal. A similar chart (Figure 25) illustrates the effect of excess perchloric acid partial pressure on the maximum number of nuclei per surface area of AP decomposition at 503 K (230 °C). The two additives work contrary to each other. Increasing ammonia concentration extends the induction period and stabilizes AP against decomposition. The presence of ammonia influences not only the number of nuclei formed at any given time (as demonstrated in Figure 26) but also the rate at which individual nuclei grow in diameter. The nuclei diameter growth rate decreases linearly as ammonia concentration increases (Figure 27).

Figure 26: Effect of ammonia partial pressure on (1) the rate dN/dt of nucleus formation, (2) the maximum number of nuclei per surface area, (3) and the induction period of AP decomposition at 503 K. (Republished and modified from [17], with the permission of © 2006 Elsevier Science and Technology Journals; permission conveyed through Copyright Clearance Center).

Figure 27: The effect of ammonia partial pressure on the rate of reaction nucleus growth during thermal decomposition of AP. (Republished and modified from [17], with the permission of © 2006 Elsevier Science and Technology Journals; permission conveyed through Copyright Clearance Center).

Heating AP in a stream of ammonia to 515 K (242°C) for 24 hours resulted in only minimal mass loss, while a sample heated under the same conditions in air lost 25.7 mass-%. The stabilization of AP by keeping it under ammonia has been used to measure the enthalpy of transition between the two polymorphic phases of AP [109].

The decomposition of AP is retarded significantly if the process is carried out in an atmosphere of ammonia [497]. The decomposition of AP was studied by DTA and isothermal TGA in the presence of air, nitrogen, perchloric acid, and ammonia. The rate of sublimation of AP was higher than the decomposition in a vacuum. In the pres-

ence of HClO_4 , the decomposition of AP was 100% complete at 623 K (350 °C) but in air, it was only 40% complete at that temperature. In the presence of NH_3 , the decomposition of AP was inhibited up to 613 K (340 °C). The addition of decomposition catalysts at the 1% level influenced mainly the second exothermic maximum at 653 K (380 °C). Catalysts had the same activities in homogeneous and heterogeneous mixtures of AP.

4.6.7 The effect of Stabilizers and Inhibitors on AP Thermal Decomposition

AP is one of the most thermally stable rocket propellant oxidizers. As such, it is not as dependent on stabilizers as some of the oxidizers (e.g., ADN, hydrazinium nitroformate (HNF)) that are trying to replace it. Other than increasing the thermal stability, some additives also reduce the burning rate of AP and prevent it from reigniting accidentally in extinguishable rocket motors.

It is regrettable that with many DTA, DSC, or TGA experiments on catalysts and stabilizers for AP, the rate of heating has not always been stated. Typical rates of heating are in the range of 5 to 10 °C/min.

AP needs to be modified to prevent or reduce the risk of inadvertent reignition of extinguishable solid rocket motors. Two methods were found that could eliminate or reduce the exothermicity of propellant grade AP exposed to temperatures of 623–663 K (350–390 °C) during soakback [368]. One was a thermal pre-treatment (see Section 4.5.3) and the other involved an additive. It was found that the temperature at which the first exotherm occurred could be raised as much as 45 °C by adding several percent of an ammonium salt (e.g., ammonium tetrafluoroborate) to the AP. The delayed exotherm was stronger than that found in AP to which no ammonium salt was added. This technique was also effective when fluorocarbon binder was in contact with the AP. Neither technique appeared to reduce the heat liberated by the deflagration of AP at 743–773 K (470–500 °C). Co-crystallized ammonium salts were also tested as AP additives. In another sample that had been catalyzed by 0.04% of a copper compound, the catalytic acceleration was suppressed via the addition of ammonium tetrafluoroborate [498, 499]. Another very effective inhibitor is ammonium hexafluorophosphate NH_4PF_6 . It was found that the temperature at which the first AP exotherm occurred could be raised 85 °C by adding 1.5% NH_4PF_6 [500]. A series of tests were conducted of the catalytic effect of traces of impurities in AP on this exotherm. Although the first AP exotherm was strongly catalyzed by as little as 0.04% of copper(II) nitrate, the catalysis was suppressed by the NH_4PF_6 additive. The burning rate was increased by adding 0.1% Cu or Zn salts. Independent tests in a combustion bomb and in a rocket motor have demonstrated the increased extinguishment reliability achieved by the NH_4PF_6 additive.

4.6.7.1 Phosphate Stabilizers

Trisodium phosphate Na_3PO_4 is a very alkaline compound (better known for its use in cleaning paintbrushes). When first mixed with AP it may cause the release of am-

monia. The isothermal decomposition of AP, with and without Na_3PO_4 , was followed thermogravimetrically at two temperatures, 541 K (268 °C = low-temperature region) and 655 K (382 °C high-temperature region). Three different samples were run at each temperature: (1) pure AP, (2) 0.1% Na_3PO_4 occluded, and (3) pure AP mechanically mixed with 10% Na_3PO_4 . Na_3PO_4 in both concentrations significantly retarded decomposition of AP at 541 K (268 °C) but not at 655 K (382 °C) [263]. DTA traces of pure AP and AP mixed with Na_3PO_4 looked essentially at the same, except that in the presence of Na_3PO_4 the LTE (at $\sim 598\text{ K} = \sim 325\text{ }^\circ\text{C}$) did not occur until 673 K (400 °C).

Various types of phosphates have been patented as stabilizers for AP and MEAP [501]. The stabilizers in amounts of 0.1 to 3% are added by co-crystallizing them with AP from concentrated solutions. Examples for phosphates for this purpose are $(\text{NH}_4)_4\text{P}_4\text{O}_{12}$, $\text{Na}_3\text{P}_3\text{O}_9$, and $\text{Na}_4\text{P}_4\text{O}_{12}$. Doubly recrystallized MEAP has a beginning exotherm at 563 K (554 °F) while stabilized MEAP with 0.5% $(\text{NH}_4)_4\text{P}_4\text{O}_{12}$ had an exotherm at 612 K (642 °F). A propellant prepared with these MEAP samples and CTPB and Al had a first exotherm at 583 K (590 °F) for the unstabilized and at 650 K (710 °F) for the stabilized oxidizer.

4.6.7.2 Carbonate Stabilizers

The burning rates of AP and AP/PS propellants are lowered in the presence of CaCO_3 and CaO . A contracting-cube equation was proposed that fits the isothermal TGA data for AP decomposition [502]. The inhibition of the LTD of AP controls the burning rates of AP/PS propellants at atmospheric pressure (see [503]).

Calcium oxide and carbonates of calcium, barium, and strontium act as burning rate inhibitors. They also delay the thermal decomposition of AP, as measured by TGA [504].

4.6.8 The Effect of Catalysts on AP Thermal Decomposition

Many inorganic and metal-organic substances catalyze the thermal decomposition of AP and accelerate its burning rate, either of AP by itself or of AP-based solid propellants. Metals can be catalytic as such or in the form of their salts or oxides [465]. Most of the burning rate catalysts currently used for AP are metal oxides. Metal-organic compounds will usually combust and release the metal oxides in a finely divided and highly reactive form.

The studies of the effect of catalysts on the rate of thermal decomposition of AP (in the absence of fuels) often run in parallel with studies on the effect of catalysts on the burning rate of AP either by itself or in combination with fuels (binders) (see Section 5.15.1). However, the catalyst activity for thermal decomposition of AP must not necessarily correlate linearly with the activity for enhancing the rate of deflagration of AP by itself or the burning rate in formulated AP-based propellants. The question remains of whether results of thermal decomposition of catalyst-AP systems or catalyst-propellant systems could be related to the burning rate of formulated composite pro-

pellants. Such a correlation would allow the use of thermal decomposition techniques (a fast technique) to screen prospective burning rate modifiers (a tedious technique) (see [505, 506] also).

4.6.8.1 The Effect of Metal Oxides on AP Thermal Decomposition

Many transition metal oxides (binary and ternary) have been evaluated as either stabilizers or burning rate catalysts for AP. In trying to decide the sequence in which the numerous references should be discussed, discussing the various metal oxides in the same sequence in which they appear in the periodic table of elements was first considered. Then we switched to a different ordering scheme and sorted the data by the number of different metal atoms in the oxide (binary and ternary oxides) and then listed them in alphabetical order.

The catalytic effect of metal oxides on the thermal decomposition of AP at temperatures below the polymorphic transition temperature has been studied extensively (typically trying to rank a series of candidate catalysts in a series of increasing activity). Testing the effects of 1 mass-% of various metal oxides added to pure AP in an isothermal decomposition apparatus [507], measuring the pressure rise in a constant volume glass apparatus, has revealed that:

1. Cu_2O , CuO , CuCl , and ZnO promote both low- and high-temperature reactions;
2. NiO and Cr_2O_3 mainly promote low-temperature reactions;
3. MnO_2 and Cu-chromite mainly promote high-temperature reactions;
4. Al_2O_3 , TiO_2 , Fe_2O_3 , and V_2O_5 are ineffective for both types of reactions.

An electron transfer theory was proposed for the [low-temperature reaction] thermal decomposition of AP and a proton transfer model was promoted for the [high-temperature reaction]. It was concluded that only p-type semiconductors of transition metal oxides are effective for the [low-temperature reaction] of AP and n-type transition metal oxide semiconductors are ineffective since Cu_2O , CuO , and NiO belong to p-type semiconductors and greatly promote the [low-temperature reaction]. On the other hand, ineffective additives such as Fe_2O_3 , TiO_2 , and Al_2O_3 , belong to the n-type. But ZnO is an exception that belongs to the n-type semiconductors. In spite of this, it had the highest catalytic activity to the AP pyrolysis, having the lowest activation energy for AP explosion ($123 \text{ kJ/mol} = 29.5 \text{ kcal/mol}$), compared to 172 kJ/mol (41 kcal/mol) for AP by itself without any catalysts. In separate tests, it was shown that MnO_2 and Cr_2O_3 promote the oxidation of NH_3 gas (a high-temperature reaction) most efficiently. In a subsequent study, the composition of the gases evolved during non-flaming decomposition of AP. This was analyzed and it was found that the presence or absence of catalysts and the type of catalysts affect the gas composition [508]. It was concluded that catalysts that produce higher concentrations of oxygen and lower concentrations of nitric oxide during the combustion of AP may increase the burning rate of AP-based propellants. The presence of nitrosyl chloride made the gas analysis more difficult. At

the same time, some catalysts were very effective in decreasing the mean molecular weight of the combustion products of AP.

A study of the kinetic laws of AP decomposition in the presence and absence of metal oxides must also take into consideration the sublimation (without decomposition) from the kinetic point of view [509]. Based on DSC thermograms, MnO_2 and CoO had a strong effect on AP decomposition, Fe_2O_3 had a weak effect, and moderately effective oxides ranked as follows: $\text{CuO} > \text{Cr}_2\text{O}_3 > \text{Co}_3\text{O}_4$.

A very good summary on the effect of metal oxides on the thermal decomposition and the burning rate of AP by itself and AP in combination with various combustible binders was published by Komarov, containing 84 references from research literature [510].

4.6.8.2 Binary Oxides

There are several dozens of publications dealing with the effect of transition metal oxides on the rate of decomposition of AP and the burning rate of propellants formulated with doped AP. It is difficult to organize this mass of technical information because most papers deal not only with one metal oxide at a time but with a group of metal oxides in a comparative study in an effort to identify the most active metal oxides. The question is if the metal oxides change the overall rate of decomposition or if they catalyze specific steps (the rate-determining steps) of the multi-step decomposition process. The other question is whether the catalytic effect is restricted to the condensed phase or if it extends to the vapor phase in the combustion zone. There is also some overlap between the following sections because some papers discuss binary oxides as well as ternary oxides and other additives. A *binary* compound is a compound that consists of a combination of two elements. There is some inconsistency; where some authors call oxides containing **two** metals [binary oxides], we call them *ternary* oxides. Table 13 gives a summary of metal oxides tested as burning rate catalysts for AP. Some of these references may be listed only in this table and nowhere else in this book. In those instances the reference is given as a footnote. For other references the field in the column under Reference may be blank; in these instances, the case reference is cited in other parts of this chapter. A good summary of the catalytic effects of a large number of metal oxides was compiled by [511]. This data is summarized in Table 14.

In a detailed study of the thermal decomposition of AP, Bircumshaw and Newman [348, 349] noted that MnO_2 exerted a pronounced catalytic effect on the decomposition. The kinetic characteristics and the products of the reaction were altered by the added oxide. The catalytic reaction occurred without concurrent sublimation, which was observed during the low-temperature 473 to 523 K (200 to 250 °C) decomposition of AP at low ambient pressure. Pure AP, when heated in a vacuum in the temperature range 473 to 513 K (200 to 240 °C) undergoes about 30% decomposition, leaving a residue that is chemically identical with the starting material. In contrast, decomposition of AP at 503 K (230 °C) in the presence of 10 mass-% MnO_2 was found to go to

completion. It was also observed that NH_3 and the basic oxide CaO inhibited the AP decomposition reaction.

The kinetics of the thermal decomposition of the mixtures of AP and MnO_2 , compressed to form a rigid pellet, were investigated in the temperature range 410 to 485 K (137 to 212 °C) [460]. It was found that the reaction occurs in two distinct stages, the first of which was the catalyzed decomposition of AP. Two kinetic equations described the process over different ranges of reactant compositions, but both produced energy of activation close to 134 kJ/mol (32 kcal/mol). A reaction mechanism was proposed in which positive hole formation comprises the initial step. The catalytic action of the oxide was ascribed to an extension of the average lifetime of a positive hole by the manganese ions of the oxide. The second stage of the reaction was shown to be the decomposition of pure AP, which was independent of the presence of a catalytic oxide.

In the temperature range of 170 to 200 °C the rate of decomposition was measured gravimetrically by determining the loss of weight of the mixture AP-catalyst as a function of the time [434]. At temperatures above 200 °C, the rate of decomposition was followed gasometrically, condensing out all the gaseous products other than oxygen and nitrogen and measuring the rate of increase of pressure in an apparatus of constant volume. The catalytic activity of several oxides tested increased in the order $\text{MgO} < \text{Cr}_2\text{O}_3 < \text{MnO}_2 < \text{Ni}_2\text{O}_3 < (\text{Co}_2\text{O}_3 + \text{Co}_3\text{O}_4)$. Based on TGA data, it was suggested that Cr_2O_3 catalyzes AP decomposition only in the gas phase. MgO was so inactive that sublimation of AP occurred before it decomposed. The time lag before ignition (under atmospheric pressure) of powdered AP in the presence of manganese dioxide and a mixture of cobalt oxides was found to depend upon the reciprocal absolute temperature by an Arrhenius type equation from which activation energies could be determined.

In the presence of copper(II) oxide, the decomposition of AP takes place at much lower temperatures than the decomposition of pure AP [461]. An increase in the defect electron concentration of copper(II) oxide catalyst (by doping with lithium oxide) accelerated the reaction rate and shortened the induction period. The opposite effect was experienced when CuO was doped with Cr_2O_3 . The effect of the defect electron concentration on the activity of the catalyst was supposed to support the theory of electron transfer in the AP decomposition mechanism. The activation energy of the decomposition between 453–473 K (180–200 °C) was 129 kJ/mol (31 kcal/mol). A similar value of 127 kJ/mol (30.5 kcal/mol) was obtained from the dependence of the time necessary to reach explosion as a function of temperature. The LTD of AP was also studied between 473–503 K (200–230 °C) and the activation energy of 171 kJ/mol (41 kcal/mol) was obtained.

Copper(II) oxide was a superior catalyst in comparison to both copper(I) oxide and copper chromite [529].

A simple theory of self-heating and its application to the system AP and Cu_2O was developed by Jacobs and Kureishy [530]. Approximations usually made using theories

of self-heating are often erroneous. It is important to point out that kinetic experiments close to the critical ignition state yield results for the fractional decomposition α as a function of time t which deviate from the kinetic law applicable at lower temperatures. Nevertheless, these $\alpha(t)$ curves can be analyzed to yield effective global rate constants which depend on the temperature of the surroundings (T_0) rather than on the temperature of the reactant (which is a function of time). A theory of self-heating using these effective rate constants was applied to the calculation of autoignition times and self-heating curves. The results were in good agreement with the experiments.

The effectiveness of Fe_2O_3 as a catalyst for the decomposition of AP depends on the quality of the Fe_2O_3 powder and the experimental conditions. Contradictory statements about the effectiveness of Fe_2O_3 as a catalyst for the decomposition of AP can be found in the existing literature. The addition of Fe_2O_3 had little effect on the rate of decomposition of AP at 483–513 K (210–240 °C), but at 518–543 K (245–270 °C) the catalytic activity was enhanced significantly [533]. However, a few years following the research conducted by Jacobs and Kureishy (1963), the same group published data showing that in the range of 473–513 K (210–240 °C), the addition of Fe_2O_3 shortened the induction period and increased the rate of decomposition of AP. Above 533 K (260 °C) the reaction became very rapid and resulted in an explosion.

Different metal oxides with different semiconductor properties were used in an attempt to prove the electron-transfer nature of AP decomposition. During a study of the effect of p-type chromium(III) oxide and n-type titanium dioxide on the initiation of the deflagration of AP, it was found that the addition of chromium(III) oxide lowers the onset of the deflagration temperature of AP by about 160° to 180 °C [462]. It was suggested that the defect electron concentration of Cr_2O_3 is key to this mechanism. The electron conductor TiO_2 is an inert substance, even when doped with WO_3 , Al_2O_3 , or BeO . The onset of deflagration temperature was, however, decreased by ~150 °C when TiO_2 was doped with a small amount of Cr_2O_3 . This was attributed to the formation of chromium ions of higher valency on the surface of titanium dioxide (a defect conducting layer). The onset of deflagration temperature for AP has been determined in the presence of both substances as well as the activation energy of the process which leads to the deflagration. The activation energy agreed with that expected for an electron transfer mechanism.

In trying to explain the mechanism of metal oxide catalysis on AP decomposition, questions have arisen about whether the metal oxides just provide a catalytic surface area (true catalysts) or if they come under attack by the perchloric acid and form metal perchlorates that may remain dispersed in the AP crystal just shortly before the flame front reaches this part of the crystal. AP powder was mixed with ZnO , PbO , or CdO in a ball mill and pelletized [559, 560]. In later studies, the decomposition of the pellets was observed under a hot stage microscope and indicated partial melting of the pellets and color changes when heated to 423–453 K (150–180 °C). When pellets were heated to 513–523 K (240–250 °C) and then cooled, they dissolved completely in water without

residue. This indicates a chemical reaction between the metal oxide and the AP. IR spectra of the AP/CdO reaction product were similar to those of $\text{Cd}(\text{ClO}_4)_2$.

Many investigators have limited their examination of the effect of metal oxide catalysts to experiments in the condensed phase. Only a few have extended their effort to look at the effect of metal oxide surface area (particle size) on the condensed-phase reaction. Similarly, very few have looked at the catalytic effects of metal oxide particles that get carried out of the burning mass into the flame front, remain suspended in the turbulent flow, and possibly catalyze reactions in the gas phase. In one set of experiments with NiO of three different particle sizes (specific surface area 2 to $36 \text{ m}^2/\text{g}$ by krypton BET), the catalyst was suspended on a fritted glass filter held in the vicinity of the subliming AP pellet such that the vapors would have to pass through the catalyst layer [524]. In a parallel test, 1% of the nickel oxide was dispersed uniformly throughout the pressed AP pellet and no catalyst was on the glass filter. In both cases, the rate of decomposition as measured by the pressure increase in a closed bomb at 523 K (250 °C) increased with the specific surface area of the particles. Similar results were obtained with copper(II) oxide. The porosity of the metal oxide particles had a significant impact on the rate of decomposition, more so than the geometrical surface area. If different weights of NiO or CuO are taken and matched in such a way that the surface areas are equal, the effect of the metal oxide impurities on the rate of AP decomposition remains the same. One per-cent of NiO powder with a surface area of $36 \text{ m}^2/\text{g}$ had the same effect as 51% of NiO with a surface area of $0.7 \text{ m}^2/\text{g}$. While many investigators have concentrated on the effects of metal oxides on the solid/molten phase AP decomposition, these experiments showed that processes in the gas phase are also affected by suspended metal oxide particles.

Transition metal oxides that can change the state of oxidation of the core metal are thought to be better catalysts than those of metals that retain the same oxidation state. Using Cr_2O_3 labeled with ^{51}Cr isotope it was attempted to determine whether the action of the additive on thermal decomposition of AP involves oxidation of chromium(III) to chromate or if the additive remains untransformed acting as a catalyst [519]. Results of experiments showed that no traces of hexavalent chromium could be detected after thermal decomposition of AP with the catalyst were added in the ratio 1:1. Moreover, it was demonstrated that if Cr_2O_3 is heated to 573–583 K (300–310 °C) in air for three hours, up to 4% of Cr_2O_3 is transformed into chromate.

The effect of a combination of metal oxide catalysts and X-ray radiation (used for diagnostics to image the progress of the flame front or coming from cosmic radiation) was studied [561]. It was noted that irradiation at the moment of decomposition accelerates the decomposition of AP containing the additives of NiO, Ni_2O_3 , and Co_3O_4 . However, this has no effect on the kinetics of the decomposition of pure AP and of AP containing additives of CdO, CdS, Fe_2O_3 , PbO, WO_3 , or MoO_2 . Existing theories on the mechanism of the effect of preceding irradiation on the subsequent thermal decomposition of AP do not explain the observed effect. X-ray irradiation may induce free radicals in the salt.

Some additives do not catalyze AP thermal decomposition by themselves. Instead, they form the active catalysts during thermal decomposition of the precursor or during its interaction with AP. As an example, a comparison of the effects of different copper salts as additives on the thermal decomposition of AP showed that the efficiency of an additive depends on the ease of its thermal decomposition [562]. The rate of thermal decomposition of AP is strongly affected by the additives which themselves can easily be decomposed or give rise to decomposition products accelerating thermal decomposition (for example, copper(II) nitrate which forms nitrogen oxides during decomposition). A comparison of 1% of copper(II) sulfate, bichromate, benzoate, oxalate, lactate, and nitrate added to AP and heated to 523 K (250 °C) showed that copper(II) nitrate had the highest catalytic effect on AP decomposition while copper(II) sulfate had the lowest.

The activity of catalysts in the thermal decomposition of AP decreased in the order of:

There is evidence that the effect of catalytic additives on the decomposition of AP is connected mainly with other reactions which may occur in this system, rather than with the catalysis of decomposition of perchloric acid (as it was initially assumed); e.g., the oxidation of ammonia using the products of decomposition of perchloric acid. The most active catalyst should be considered to be the catalyst capable of accelerating both the decomposition of the acid and the oxidation of ammonia [492].

A model of the catalysis of the burning of sublimable solid single-component propellants was developed on the basis of a study of combustion in the system $\text{HClO}_4\text{-NH}_3\text{-Fe}_2\text{O}_3$ [563]. If AP is burned without catalysts, the decomposition rate is proportional to the surface area and pressure. The model of heterogeneous catalysis of AP burning predicts an increase in burning rate with a decrease of the radius of the catalyst grains. The increase in the burning rate was very distinct when the radius decreased to $<0.2\mu\text{m}$. The maximum increase in the reaction rate occurred at a catalyst concentration of 4 mass-%. The methods and models of calculation are general in nature and can just as well be used to calculate the burning rate of other perchlorates with other catalysts.

The question that is often asked is whether the addition of catalysts catalyzes the decomposition of ammonia or the decomposition of perchloric acid once the AP salt dissociates into its constituents in the flame front. In order to answer such questions, experiments have been conducted with catalysts applied to HClO_4 -supported flames and with catalysts applied to NH_3 -supported flames [564].

AP decomposition in the presence of various metal oxides (MnO , Cu_2O , CuO , Cr_2O_3 , Fe_2O_3 , CoO , and Co_3O_4) at 1, 5, and 10% was studied by DSC [565, 566]. A general kinetic law was used in interpreting the results from experimental runs. It was observed that in the catalytic decomposition of AP, several reactions occur and contribute to the overall kinetic law. The relative contributions of these reactions

and the actual kinetic parameters (apparent order of reaction, Arrhenius factors, activation energies) were evaluated.

The effect of the addition of 0.1–5% CaO on the combustion and thermal decomposition of AP was studied in a strand burner closed bomb and by DTA [567]. Pressed pellets were burned in plexiglass tubes at 5.05–101 MPa (50–1000 atm). The particle size of the AP powder was $<250\text{ }\mu\text{m}$ and that of the CaO additive was $<100\text{ }\mu\text{m}$.

Comparison of the activation energies for uncatalyzed thermal decomposition of AP with that of powdered AP catalyzed by low concentrations of MnO_2 showed that the rate-determining step for the catalyzed reaction is electron transfer from NH_4^+ to ClO_4^- [541]. The effectiveness of the catalyst is increased by baking the mixture for two weeks at 323 K (50 °C) during which Mn^{2+} or Mn^{4+} ions enter the NH_4ClO_4 lattice.

Vacuum pyrolysis of AP and AP/PS propellants was studied by DTA to measure the effects of transition metal oxides on decomposition and sublimation [542]. Being competitive processes, sublimation and decomposition proportions depend mostly on the pressure of the pyrolysis chamber and also on particle size and the presence or absence of contaminants. Literature data on the enthalpies for complete decomposition and complete sublimation were compared to the results of DTA peak area measurements to calculate the relative extents of sublimation and decomposition for AP by itself and the propellant mixture. For AP by itself and in the absence of catalysts, the extent of sublimation increased with a decrease in particle size. For propellants, the powder sublimed more readily than the bulk material. However, in the presence of metal ions, the bulk material sublimed more readily than the powder. To substantiate this finding, the effect of MnO_2 on NH_4ClO_4 sublimation as a function of particle size was examined. Surprisingly, the extent of sublimation decreased as the MnO_2 particle size decreased.

The kinetics of the thermal decomposition of AP were studied in the presence and absence of rare earth oxide catalysts, yttrium oxide (Y_2O_3), and lanthanum oxide (La_2O_3) [537]. The Prout-Tompkins and contracting-cube ($n = 3$) equations were found to fit the TGA data for the catalyzed thermal decomposition of AP. An attempt was made to use matrix isolation techniques and IR spectroscopy to identify the gases that evolved at different temperatures during the decomposition in the presence and absence of catalysts. The mechanism of the catalyzed thermal decomposition of AP has also been discussed in [537] in terms of an electron transfer process.

IR spectral investigations of AP were conducted over the temperature range of 298–563 K (25–290 °C). This was done in the absence [382] and the presence [532] of varying amounts of ammonium permanganate and using 2% by weight of different rare earth oxide additives. Heating and spectral scanning were done simultaneously, and the peak intensity was presumed to be proportional to the amount of undecomposed AP. The presence of 10% ammonium permanganate lowered the temperature of AP decomposition from 473 to 383 K (200 to 110 °C) and increased the rate by several times. It was theorized that mixed oxides produced as a result of deflagration of ammonium permanganate were catalyzing the process. In the presence of rare earth oxides

additives, the NH_4^+ stretching peak intensity decreased considerably. The extent followed the trend $\text{Gd}_2\text{O}_3 > \text{MnO}_2 > \text{Nd}_2\text{O}_3 > \text{Pr}_2\text{O}_3 > \text{Dy}_2\text{O}_3 > \text{Y}_2\text{O}_3 > \text{La}_2\text{O}_3 > \text{virgin AP}$. An electron transfer mechanism was proposed to explain these results.

The catalytic activity of nanocrystalline transition metal oxides on the decomposition of AP was investigated using thermal analysis [568]. Results indicated that nanocrystalline CuO powders have a strong catalytic activity compared to other metal oxides. The catalytic activity of nanocrystalline CuO powders during the decomposition of AP depended on the methods of preparation and the micro-structure of the resultant nanocrystalline CuO powders. Among them, the catalytic effect of spherical shape finely dispersed nanocrystal CuO powders on AP decomposition was the strongest, and it was able to reduce the onset of the higher temperature peak of AP decomposition down to 366 K (93°C). At the same time, the exotherm increased by 590 J/g to 1420 J/g. Nanocrystalline Fe_2O_3 doped with 5% Cu₂O has an even greater catalytic activity during the decomposition of AP. It reduced the onset temperature of the higher exothermic peak of AP decomposition by 35°C down to as low as 351 K (78°C) and the exotherm increased by 980 J/g to reach 1230 J/g. Compared to binary metal oxides, some new ternary metal oxides have the best catalytic activities.

The catalytic effects of superfine transition metal oxides on the thermal decomposition of AP were studied by DTA [569]. Results showed that both the single transition metal oxides (Co_2O_3 , CuO, Fe_2O_3) and the composite oxides ($\text{Fe}_2\text{O}_3/\text{Co}_2\text{O}_3$, CuO/ Co_2O_3 , $\text{Fe}_2\text{O}_3/\text{CuO}$) have catalytic effects on the thermal decomposition of AP. From the curves of the temperature change of the higher exothermic peak of AP decomposition which is a function of the content of one of the composite transition metal oxides, an optimum mixture ratio ($\text{Fe}_2\text{O}_3 : \text{Co}_2\text{O}_3 = 1 : 3$) was found.

NiO nanoparticles with an average particle size of 10 nm were characterized by XRD, FTIR, and TEM [552]. The catalytic effect of the NiO nanoparticles on the thermal decomposition of AP was measured by DTA and TGA. The catalytic activity of nano-size NiO was superior to that of bulk NiO powder. Adding 2% of nano-NiO to AP decreased the decomposition temperature by 93°C and increased the heat of decomposition from 590 to 1490 J/g.

The crystal phase, morphology, and particle size of Co_3O_4 nano-powders with different average crystallite sizes (23, 30, 35, and 150 nm) were characterized by XRD and TEM [514]. The catalytic activity of nano-size Co_3O_4 in the decomposition of AP was investigated using DTA to make comparisons with micron-size Co_3O_4 . It was found that the nano-size Co_3O_4 made the temperature of the lower-temperature exothermic peak of AP disappear. It also decreased the onset temperature of the higher-temperature exothermic peak by 128°C. The exothermicity increased from 515 to 1265 J/g. Nano-size Co_3O_4 produced better catalytic activity for the thermal decomposition of AP than micron-size Co_3O_4 .

Nano-size Fe_2O_3 as a catalyst has been tested before in solid propellants. However, the problem is that nanoparticles of Fe_2O_3 prepared using the traditional wet method aggregates in water and cannot be distributed homogeneously in the solid propellant,

which leads to a decrease in the catalytic activity. To solve the aggregation problem, nanoparticles of Fe_2O_3 were prepared in an oil/water two-phase system and characterized by XRD and FTIR [570, 571]. Amorphous nanoparticles with a narrow particle size distribution (12 nm) were obtained using this method. DTA showed that the two exothermic peaks of AP decomposition with micrometer-sized Fe_2O_3 shifted to temperatures 110 and 62 °C lower than those of pure AP, respectively. The temperatures of the two peaks of AP with nanometer-sized Fe_2O_3 decreased by 89 and 118 °C, respectively. This means the catalytic performance of nanometer-size Fe_2O_3 is superior to that of micrometer-sized Fe_2O_3 . With the increasing content of nanometer-size Fe_2O_3 , the temperature of the second exothermic peak of AP decreased even more. The temperature of the first exothermic peak of AP did not change too much when the content of nanometer-size Fe_2O_3 was 1% or 2.5%. However, it decreased significantly when the Fe_2O_3 content was close to 5%.

Cu_2O nanocrystals were prepared using precipitation from $\text{Cu}(\text{NO}_3)_2$ and NaOH and tested as catalysts for the AP thermal decomposition [531]. Hydrazine hydrate was used as the reducing agent. The as-prepared Cu_2O nanocrystals were characterized by XRD, TEM, and XPS. The catalytic activity of the Cu_2O nanocrystals of different morphology for the AP decomposition was measured using DTA. Cu_2O nanocrystals with different morphology revealed different catalytic effects on the AP decomposition. The addition of 2% polygonal Cu_2O nanocrystals to AP decreased the upper onset temperature of AP decomposition by 103 °C and increased the exothermicity of decomposition from 590 to 1350 J/g.

CuO nanocrystals and nanorods were explored as catalysts for the decomposition of AP [525, 572]. AP typically undergoes a two-stage decomposition process. The addition of CuO nanocrystals led to a downshift of the high-temperature stage of AP decomposition towards lower temperatures.

In a similar way, the thermal decomposition of AP can be accelerated to varying degrees by adding NiO nanocrystals with different surface areas [551]. With increasing annealing temperatures, the BET surface areas of NiO samples were reduced from 108.6 to 0.9 m²/g. The catalytic activities of NiO nanocrystals on the thermal decomposition of AP were investigated using TGA/DTA. With the addition of NiO nanocrystals, the onset temperature of the thermal decomposition of AP decreased greatly. Larger surface areas of NiO nanocrystals promoted the thermal decomposition of AP more actively than coarse, low-surface area materials.

Nanorods and micro-octahedrons of $\alpha\text{-Fe}_2\text{O}_3$ were selectively synthesized through a one-step hydrothermal treatment of iron(III) chloride [535]. The resulting samples were characterized using XRD, SEM, TEM, and FTIR. It was found that monodispersed nanorods were 10–25 nm in diameter and 50–100 nm in length, while the octahedrons were 100–400 nm in size. These $\alpha\text{-Fe}_2\text{O}_3$ nanorods and micro-octahedrons exhibited quite different catalytic activity on the thermal decomposition of AP. The nanorods significantly reduced the decomposition temperature of AP, but the micro-octahedrons did not.

The catalytic effect of two different sizes of α -Fe₂O₃ nanoparticles on the thermal decomposition of AP was investigated using DSC [573]. The nano-sized Fe₂O₃ particles exhibited more of a catalytic effect on the thermal decomposition of AP than commercial Fe₂O₃ particles. The addition of 2 mass-% of α -Fe₂O₃ particles with a very fine size of 3.5 nm lowered the HTD of AP by 59 °C. The enthalpy of the reaction was 4.574 kJ/g compared to 0.834 kJ/g of uncatalyzed AP and the activation energy was reduced.

Using 1,2-epoxypropane (propylene oxide) as the agent for accelerating the hydrolysis of Fe(III) ions or Fe(III) alkoxylates, an AP/Fe₂O₃ wet gel was prepared using a sol-gel method, and an AP/Fe₂O₃ aerogel was obtained using a supercritical extraction of the solvent [574]. Both pH and NMR studies suggest that the added epoxide acts as an irreversible proton scavenger that induces the Fe(III) species to undergo hydrolysis and condensation to form an inorganic iron oxide framework. This method can be extended to prepare other transition- and main-group metal oxide nanomaterials. The samples were characterized using TEM, SEM, energy dispersive spectroscopy (EDS), and DSC. The results indicated that the aerogels are nanocomposites, in which the particle size of AP is 50–90 nm and the particle size of Fe₂O₃ is about 20 nm. The impact sensitivity of AP/Fe₂O₃ is higher and the friction sensitivity is lower than that of pure AP. The peak temperature for thermal decomposition of AP/Fe₂O₃ is much lower, and the rate of heat release is much faster. For example, in AP/Fe₂O₃ containing 90% of AP, the high and low decomposition peaks are shifted downward by 125 °C and 113 °C, respectively, compared to those of pure AP, and the rate of heat release is four times faster.

Different shapes of CuO nanocrystals were synthesized and tested for their activity in AP decomposition [575–577]. CuO in its various crystalline shapes lowered the onset of decomposition temperature of AP in all cases.

Nanoparticles of CuO, Mn₂O₃, Cr₂O₃, and Fe₂O₃ have been characterized using XRD which indicated an average particle diameter of 35–54 nm [578]. Their catalytic activity in the thermal decomposition of AP was then measured using DTA. AP undergoes a two-step decomposition process where the addition of metal oxide nanocrystals causes a shift of the HTD exothermic peak toward lower temperatures.

Nano-size iron(III) oxide in the shape of nanotubes is a particularly effective catalyst for the decomposition of AP [579]. The highly crystalline α -Fe₂O₃ nanotubes were about 200–1000 nm long, 100–150 nm wide, and the wall thickness was 25–30 nm. A detailed reaction mechanism for AP decomposition over α -Fe₂O₃ nanotubes was proposed.

The effect of the specific surface area of TiO₂ catalysts on the thermal decomposition characteristics of AP was examined with a series of thermal analysis experiments [580]. It was evident that the thermal decomposition temperature of AP decreased when the specific surface area of TiO₂ increased. It might also be possible that TiO₂ influences the frequency factor of AP decomposition because there was no observable effect on the activation energy.

Nano-size NiO/MgO particles were prepared via an impregnation method [581]. The phase and morphology of NiO/MgO catalysts were characterized using XRD, TEM, and energy dispersive X-ray analysis (EDAX) spectroscopy. The catalytic effect of nanometer particles (NiO, MgO alone), NiO+MgO dry mixture particles, and NiO/MgO composite particles on the thermal decomposition of AP was investigated using DSC. The results revealed that NiO particles are highly dispersed on the MgO support. Catalytic performance of the nano-size NiO/MgO composite particles was superior to that of corresponding single ingredients or NiO+MgO dry mixture particles. Nano-size NiO/MgO can make the HTD peak value of AP decrease by 92°C. The temperature difference between the low- and HTD peak shrinks by up to 10.6°C, which indicates good catalytic performance. The MgO support can effectively prevent the aggregation of NiO particles and increase the number of active sites.

Iron(III) oxide, Fe_2O_3 , is a well-known catalyst for the thermal decomposition of AP and is extensively used as a burning rate modifier for AP-based composite solid propellants. The particle size of conventional propellant grade iron(III) oxide was reduced to nano levels via continuous ball milling using a planetary ball mill employing zircon balls in isopropyl alcohol [582]. The batches of nano ferric oxide prepared by varying the ball milling parameters, viz., time and sample mass were characterized using a particle size analyzer, surface area analyzer, and XRD. Lewis acid sites present in the catalyst were determined using a butylamine desorption technique. The catalytic activity of nano ferric oxide samples was evaluated from the thermal decomposition of AP mixed with iron(III) oxide using TG-DTA. The catalytic activity of different batches of Fe_2O_3 was correlated with their surface properties. It was found that continuous ball milling reduced the particle size of Fe_2O_3 to nano levels and the particle size of conventional Fe_2O_3 was reduced from 138 nm to 72 nm after 40 hours of wet ball milling in isopropyl alcohol. The onset of thermal decomposition of AP was reduced from 406 K (133°C) to 339 K (66°C) with the addition of nano- Fe_2O_3 .

The effect of metal oxides, mixed oxides, binary and ternary ferrites, and rare earth metal oxides in the shape of nano-oxides on the thermal decomposition AP has been studied in detail, including assessing the influence of the size of oxides on the thermal decomposition of AP and a comparison of bulk and nano-sized oxides [583]. The size distribution, morphology, and nanostructure of metal oxide nanoparticles are very important characteristics and they do affect the kinetics of the decomposition of AP. Due to the small size and the large surface area, nano-sized metal oxides are more active catalysts on the thermal decomposition of AP compared to their bulk size oxides with the same chemical composition.

Iron oxides which are often used as a burning rate catalyst for all types of composite propellants are polymorphous crystalline minerals, including hematite ($\alpha\text{-Fe}_2\text{O}_3$), magnetite (Fe_3O_4), and maghemite ($\gamma\text{-Fe}_2\text{O}_3$). Nanoparticulate materials such as hematite and maghemite exhibit high catalytic activity during the thermal decomposition of AP. The catalytic effect of iron oxide nanoparticles was attributed

to their small particle size, more active sites, and high surface area which enable gas adsorption of released products during the thermal reactions. Methods for obtaining nanoparticulate iron oxides and the advantages of the different techniques for characterizing these nanomaterials have been summarized [584]. The morphologies and structures as well as the textural properties created by physical adsorption can be characterized using TEM, SEM, XRD, and FTIR.

4.6.8.3 Ternary Oxides

A *ternary* compound is a compound that consists of a combination of three elements, one of them being oxygen. There is some inconsistency in existing literature; sometimes oxides containing **two** different metals and oxygen are called [binary oxides] but here we call them *ternary* oxides. Table 15 is a summary of ternary metal oxides tested as catalysts for AP decomposition.

Table 15: Summary of ternary metal oxides tested for AP decomposition.

Sorted alphabetically by metal oxide formula, then by year.

At low temperatures between 489 to 550 K (216–277°C), carbon had no effect on the rate of decomposition of AP. However, copper chromite, either alone or with carbon, exerted a slightly positive catalytic effect, the rate constants for mixtures being about 50% greater than those for the pure salt at corresponding temperatures [597]. The activation energy was unchanged at 129.7 kJ/mol (31 kcal/mol). When copper chromite, cupric oxide, or potassium dichromate was mixed with AP, the rate of the high-temperature reaction was considerably enhanced. The activation energy was the same for all the catalysts tried, viz., 200.8 kJ/mol (48 kcal/mol).

Under government contracts, SRI conducted a series of experiments to study the effect of copper chromite and other mixed metal oxides on the decomposition of AP and AP/fuel mixtures. Among others, they also separated the effects of the catalyst on the decomposition of AP and the subsequent combustion of ammonia in an atmosphere containing HClO_4 . At first, the kinetics of decomposition of AP was studied in detail by itself (without the addition of catalysts). Following that, the addition of copper chromite as a catalyst was studied and reaction mechanisms for both uncatalyzed and catalyzed decomposition was proposed [598].

The rate of heat release during AP decomposition is controlled via the absence or presence of catalysts. The rate of heat release of AP-fuel or AP-catalyst mixtures (both under adiabatic conditions) was studied as a function of temperature [599, 600]. In the presence of catalysts, the autocatalytic feature associated with the nucleation of pure AP disappeared and the adiabatic reaction kinetics followed an Arrhenius-type behavior. Experiments with AP-fuel mixtures showed that measurable heat release occurred at temperatures below the phase transition temperature of AP and that the rate of heat generation per mass of material is greater than that of pure AP, but the data were less reproducible than for pure AP. The rate of exothermic decomposition of pure AP was unaffected by an increase in pressure. This observation suggested that the heat release is controlled using homogeneous or heterogeneous reactions in the condensed phase.

Therefore, the role of condensed-phase reactions in the ignition and deflagration of AP propellants was examined in more detail [601, 602]. A thermal runaway in the condensed phase can account for the ignition phenomena observed. Also, at low steady-state deflagration rates, the contribution of the solid-phase reactions can be illustrated. Some of the propellants quenched during deflagration revealed the existence of a subsurface layer, which was located in a zone at which the temperature had reached a level characteristic of the polymorphic crystal transition of AP.

The action of copper chromite catalyst in contact with solid AP differs markedly from that of the catalyst in contact with the gaseous dissociation products of AP [603]. On exposure to ammonia and perchloric acid at 675 K, the catalyst loses its activity rapidly. This may be due to the oxidation of chromium cation from the plus 3 oxidation state to a higher oxidation state.

The oxidation of ammonia using HClO_4 catalyzed by copper(II) chromite (CuCr_2O_4) and copper(I) chromite ($\text{Cu}_2\text{O} \cdot \text{Cr}_2\text{O}_3$) was studied in order to examine

the role of the copper ion valence state [604]. The results at 673 K (400 °C) indicated that Cu^{2+} is a much better catalyst than Cu^{1+} for this reaction. Similar considerations apply to the complete oxidation of olefinic hydrocarbons such as those in polymeric binders. It was suggested that cupric chromite plays a dual function of catalyzing the decomposition of AP and the oxidation of ammonia and other fuel molecules. Additional experiments spanning the temperature range of 250 °C to 325 °C also studied the effect of copper chromite on the rate of AP decomposition [459].

The kinetics of AP/hydrocarbon fuel and AP/ammonia reactions were studied by passing the fuel gas over granular AP (with and without a copper chromite catalyst) in a reactor at low pressures (17 mm Hg), while slowly raising the reactor temperature and analyzing the exhaust gases (after the removal of corrosive HCl) in a mass spectrometer [605]. They have concentrated on a quantitative examination of the potential contribution of surface-catalyzed reactions between AP, catalyst, and gaseous organic molecules, representative of the fuel binder in an operational propellant. Propylene gas was used as a simulant for hydrocarbon binders. Tests were performed without and with 2.9 or 4.8 mass-% catalyst in the AP. In an uncatalyzed system, reactions between NH_3 and HClO_4 in the gas phase determined some of the kinetics, but in the presence of the catalyst, the role of these reactions diminishes. Both the CuO and CuCr_2O_4 catalysts catalyzed the complete oxidation of hydrocarbons and the oxidation of ammonia, reactions which would be encountered in a propellant composed of AP/ CuCr_2O_4 /binder. Surface-catalyzed reactions would be expected to play an important part in both ignition and combustion of such propellants. One application of the results may be with regards to the evaluation of the surface temperature of an AP/ CuCr_2O_4 propellant on the basis of the kinetic information. For a specified regression rate, the surface temperature of the solid may be estimated by examining the data for the mass consumption rate of solid AP/ CuCr_2O_4 as a function of temperature. For AP/4.8 CuCr_2O_4 , it was found that for the linear regression rate of 0.04 cm/sec (corresponding to a mass consumption rate of 0.0012 mol/sec), the surface temperature would be between 640 and 660 K (depending on the stoichiometry employed). These values were in good agreement with experimental observations.

A different experimental setup was used in an opposing flow burner, where a flow of combustible gas (e.g., methane) impinges on a solid surface of AP (with or without a catalyst embedded in the solid oxidizer) [606]. This is similar to the process in an inversed hybrid rocket where a gaseous (or liquid) fuel passes over a solid oxidizer. A diffusion flame is established in the stagnation region formed by the two counter-current flows of reactants. The solid AP cylinder can be slowly advanced toward the source of the fuel. The trick is to match the rate of advance of the propellant strand to its consumption rate so that the distance between the gaseous fuel outlet and the propellant surface remains constant. With increasing mass flux of gaseous fuel, the mass flux of solid AP (with or without a catalyst embedded in the solid oxidizer) grows until a limiting condition is reached that is governed by the kinetics of the reaction and the mass transfer to/from the surface. Further enhancement in fuel flow does not result

in an increase in the mass consumption rate of the solid oxidizer. One of the variables studied was the catalyst concentration in the oxidizer. The critical mass flux m^* corresponding to the limiting rate of propellant consumption increased significantly as the catalyst concentration in the solid phase was increased from 0 to 5 mass-% (see [607] also).

The most effective catalysts from a group of spinels and ferrites were CuCr_2O_4 and CuFe_2O_4 , indicating that the copper entity is the active part of the molecule [589]. These catalysts were tested with AP by themselves, as well as in a composite propellant containing 20% butyl rubber. Catalyst additions were at 1%. Testing was done at 2.02, 4.04, and 6.06 MPa (20, 40, and 60 atm). The best catalyst was CuCr_2O_4 at any pressure, followed by NiCr_2O_4 and CuFe_2O_4 for the high-pressure tests.

The addition of dichromate ions introduced into the lattice of AP is likely to play a dual role. At the point where the dichromate has not yet decomposed (which occurs at the initial stages of the process), it is an active proton acceptor and so inhibits the formation of reaction nuclei [608]. While the degree of AP decomposition increases, especially at high temperatures, the dichromate ion decomposes. The product of this reaction chromium(III) oxide can cause heterogeneous catalytic action on the rate of thermolysis of AP.

DTA of powdered AP, PS, and AP/PS propellant, catalyzed using small amounts (1 mass-%) of freshly-prepared CuCr_2O_4 and mixtures of CuCr_2O_4 and CuO revealed that decomposition is increased due to heterogeneous catalysis [609]. The kinetics of thermal decomposition of AP in the orthorhombic region of AP by itself with and without CuCr_2O_4 were studied as baseline.

Variable temperature (303–553 K) IR spectroscopic studies were conducted during the thermal decomposition of pure and γ -treated AP [382]. Decomposition was enhanced using γ -radiation or when in the presence of an additive such as Gd_2O_3 . The intensity of the stretching $\sim 1100\text{ cm}^{-1}$ and bending $\sim 625\text{ cm}^{-1}$ frequencies of ClO_4^- decreased upon heating the KBr matrix even below 360 K. Above this temperature, a broad band developed over a band of $480\text{--}510\text{ cm}^{-1}$ in the pure and γ -treated AP, which was attributed to the $\text{ClO}_3^- \nu_4$ vibration.

The catalytic activity of mixed $\text{CuO-Cr}_2\text{O}_3$ oxides on the thermal decomposition of AP was investigated using DTA, electrical conductivity measurements, and XRD techniques [610]. The results indicated that the decrease in the defect electron sites of a CuO catalyst doped with 1 atom-% Cr^{3+} inhibited its activity, while the opposite effect was observed when Cr_2O_3 was doped with 1 atom-% Cu^{2+} . A catalyst containing 70 atom-% Cr^{3+} was found to be the most active during the decomposition of AP. At this Cu:Cr ratio, CuCr_2O_4 formation was demonstrated by XRD. The activity of this spinel was explained on the basis of a hopping electron mechanism between $\text{Cr}^{3+}/\text{Cr}^{4+}$ active sites.

Six metal oxides (CdO , Cr_2O_3 , Co_3O_4 , NiO , CuO , and MoO_3) were prepared using calcination of the corresponding precursors at 773 K (500 °C) for five hours in air and were tested as catalysts for AP decomposition [611]. The acidities and basicities

of these metal oxides were estimated using the adsorption of pyridine or formic acid vapor. The pyrolysis of pure AP and AP mixed with 10 mass-% metal oxide was studied in a dynamic atmosphere with GN_2 purge using TGA (heating rate $5^\circ\text{C}/\text{min.}$) and also by using derivative thermogravimetric analysis. Based on the TGA trace, the low-temperature pyrolysis (LTP) of pure AP started at 568 K (295°C) and high-temperature pyrolysis (HTP) was completed at $\sim 603\text{ K}$ ($\sim 330^\circ\text{C}$). The second step followed in the range of 608 to 638 K ($335\text{--}365^\circ\text{C}$). The differential TGA revealed two peaks; one at 580 K (307°C) and one at 622 K (349°C). The addition of Cr_2O_3 , Co_3O_4 , CuO , and MoO_3 reduced the two pyrolysis stages to one step, which started at 533–558 K ($260\text{--}285^\circ\text{C}$) and finished at 603 to 643 K ($330\text{ to }370^\circ\text{C}$). The lowest completion temperature was with Cr_2O_3 . CdO and NiO retained the two-step decomposition. The oxides can be divided into acidic and basic oxides. A correlation was found between the catalytic activities of the metal oxides during the pyrolysis of AP and their acid-base characters. The higher the ratio of basicity to acidity, the more active the oxide is during the pyrolysis of AP. Cr_2O_3 was the most active and NiO was the least active in this group of basic oxides. The activation energies of the non-catalyzed and catalyzed pyrolysis of AP were calculated from the TGA results. The activation energy of pure AP decomposition was 170 kJ/mol for LTP and 145 kJ/mol for HTP. In all cases, the activation energy of pure AP decomposition was lowered by adding metal oxide catalysts.

Thermal analysis of LaCoO_3 nanocrystals with pure perovskite structure showed a strong catalytic effect on the AP decomposition [612]. The catalytic effect was more pronounced with the increased content of LaCoO_3 nanocrystals in the AP. Adding 2% of LaCoO_3 nanocrystals decreased the upper temperature of AP decomposition by 108°C and increased the exothermic enthalpy of decomposition from 590 to 1390 J/g. When the content of LaCoO_3 was increased to 5%, the upper temperature of AP decomposition decreased by 116°C , and the enthalpy of decomposition increased to 1600 J/g.

The catalytic effect of CuCr_2O_4 on the thermal decomposition of AP as a function of catalyst concentration was investigated using DSC [523]. Addition of a small amount, only 2 mass-% of the nano- CuCr_2O_4 showed the best catalytic effects as compared to nano- CuO in lowering the upper decomposition temperature by 118°C . High heat releases of 5.4 and 3.9 kJ/g were observed in the presence of nano- CuO and CuCr_2O_4 , respectively. A mechanism based on an electron transfer process was proposed for AP decomposition in the presence of nano-metal oxides.

Nanocrystallites of six mixed ternary transition metal ferrites (MTTMF) were prepared using co-precipitation and characterized using XRD and BET [587]. XRD patterns produced average particle sizes of 3 to 7 nm. Catalytic activities of MTTMF's on the thermal decomposition of AP were investigated using TGA, DSC, DTA, and ignition delay measurements. The catalytic activity was found to decrease in the following order: $\text{CoZnFe}_2\text{O}_4 > \text{CoNiFe}_2\text{O}_4 > \text{CuZnFe}_2\text{O}_4 > \text{CuCoFe}_2\text{O}_4 > \text{NiCuFe}_2\text{O}_4 > \text{NiZnFe}_2\text{O}_4$.

Adding 2% of NdCrO_3 nanoparticles to AP decreased the onset temperature of thermal decomposition by 87°C and increased the heat of decomposition from 590 to 1073 J/g [595].

Binary transition metal ferrite nanocrystals MFe_2O_4 ($M = Cu, Co, Ni$) were prepared using a co-precipitation method and were characterized using XRD, which produced average particle sizes ranging from 27 to 44 nm. The catalytic activity for AP decomposition measured using TGA, DTA, and ignition delay were used to evaluate kinetic parameters by model fitting as well as an isoconversional method [613].

Since both zinc oxide and titanium oxide were said to be good catalysts for AP decomposition, it was logical to test a ternary oxide containing both. Nano-size $ZnTiO_3$ powders were prepared by means of a precipitation method using $TiCl_4$, $Zn(NO_3)_2 \cdot 6H_2O$, and $(NH_4)_2CO_3$ as starting materials [614]. The $ZnTiO_3$ nanocrystals were characterized using XRD, FTIR, and TEM. The catalytic performance of $ZnTiO_3$ nanocrystals for AP decomposition was investigated using DTA. The $ZnTiO_3$ powder had a spheroidal shape with particle sizes of about 100 nm. The low- and HTD peaks of AP were decreased by 18.3 and 25.1 °C respectively when adding 5% nano- $ZnTiO_3$ powder. With increasing nano- $ZnTiO_3$ content in AP, the catalytic effects of $ZnTiO_3$ powders on the HTD of AP were enhanced and the catalytic effects of the LTD of AP were reduced.

Cu/Fe mixed oxides were prepared via calcination of Cu/Fe hydrotalcite precursors and tested as catalysts for the thermal decomposition of AP by measuring their catalytic activity using TGA and DTA [615]. The onset of exotherm of AP decomposition was lowered by the addition of 4 mass-% Cu/Fe-mixed oxides at a temperature of 104 °C. Higher catalyst concentrations favored the further decomposition of AP. The proposed catalytic mechanism is the presence of O_2^- on the surface of Cu/Fe mixed oxides, which can accelerate the thermal decomposition of AP.

Nano-size $CoFe_2O_4$ was synthesized by a polyol-medium solvothermal method and characterized using XRD, TEM, and selected area electron diffraction. The catalytic activity and kinetic parameters of $CoFe_2O_4$ nanocrystallites on the thermal decomposition of AP were investigated using TGA-DSC [586]. The decrease in the activation energy and the increase in the rate constant for AP decomposition are a measure for the catalytic activity of these $CoFe_2O_4$ nanocrystallites. The catalytic effect of $CoFe_2O_4$ is noticeable, not only during the HTD process but also during the LTD process. The addition of 5% $CoFe_2O_4$ lowered the activation energy of AP decomposition from 178 to 106.5 kJ/mol and the maximum of the high-temperature exotherm was shifted from 706 K (433 °C) down to 580 K (307 °C).

The catalytic activity of nanometer-size CuO, Fe_2O_3 , and CuO/ Fe_2O_3 on AP thermal decomposition was investigated using TGA-DTA and burning rate measurements [616]. The order of the decreasing catalytic activity was $CuO/Fe_2O_3 > CuO > Fe_2O_3$. The catalytic activity of CuO/ Fe_2O_3 was better than that of CuO or Fe_2O_3 alone, which was attributed to a synergistic effect of the mixed oxides.

Nanocrystalline $Co_xZn_{1-x}Cr_2O_4$ ($x = 0.7, 0.8, 0.9, 0.95$, and 1) was synthesized via a low-temperature combustion synthesis method using citric acid as reductant and metal nitrates as oxidants. It was characterized using XRD, TEM, FTIR, DSC, and catalytic performance for AP decomposition [617]. Results revealed that the

cubic spinel-type solid solution of 30 nm $\text{Co}_x\text{Zn}_{1-x}\text{Cr}_2\text{O}_4$ particles can be obtained at 1073 K (800 °C). Compared with the thermal decomposition of pure AP, adding $\text{Co}_x\text{Zn}_{1-x}\text{Cr}_2\text{O}_4$ nanoparticles to AP decreased its decomposition temperature by 58–68 °C and increased its apparent decomposition heat to 1049–740 J/g, exhibiting a significant catalytic effect.

The effect of ferrite nanoparticles on the thermal decomposition of AP was studied using TGA and DSC [618]. Nanoferrite nanoparticles such as Zn, Mn, Ni, Co, and Cu ferrite had been prepared using a co-precipitation method. All nanoparticles were characterized using XRD and SEM. The average particle sizes were 6.8 to 1.1 nm. Activation energies of HTDs of different mixed oxide nanoparticles were calculated using the Kissinger equation. The catalytic activity of nanoferrites is very sensitive to oxygen and may be effective to improve the thermal decomposition and burning rate of AP-based propellants.

A copper chromite-based burning rate catalyst for composite solid propellants was synthesized using the thermal decomposition of basic copper ethylammino chromate [619]. The course of thermal decomposition of the precursor to copper chromite was examined using DSC-TGA and the volatile products formed were analyzed using TGA-MS. Copper content, surface area, and Lewis acid sites of the catalyst were higher than those in standard copper chromite. XRD analysis showed the presence of CuCrO_2 phases along with CuO and CuCr_2O_4 . The improved surface properties, as well as the synergetic action of three phases of oxides (CuO , CuCr_2O_4 , and CuCrO_2) in the system, increased the catalytic activity of this catalyst, resulting in a reduction of 60 °C in the onset of the decomposition temperature of AP.

Copper chromite in intimate contact with AP may undergo slow chemical changes during aging. Aging is an irreversible process during which the material undergoes a series of slow chemical degradation/oxidation reactions. AP-copper chromite (AP-CC) pellets were aged by subjecting them to temperature cycling and the effect of aging on the linear burn rate was measured [620]. Aging of individual ingredients had no effect on the burn rate, but the burn rate of AP-CC pellets was reduced when AP+CC were aged together. Changes in the properties of copper chromite during aging were identified using XRD and EDS analysis.

Four different perovskites, namely LaCoO_3 , La_2CuO_4 , LaMnO_3 , and LaNiO_3 , were prepared using a co-precipitation method and then used to catalyze the decomposition of AP [592]. LaCoO_3 exhibited the best catalytic performance among all the perovskites tested. The decomposition temperature of AP lowered to 574 K (301 °C) (115 °C lower than pure AP) and the heat release increased from 768 to 1428 J/g.

4.6.8.4 The Effect of Metal Chlorides on AP Thermal Decomposition

The low-temperature thermal decomposition of AP can be initiated using a single-stage nucleation process at a lattice defect site on the surface of the crystal. If the crystals are allowed to age for several days after inducing the lattice defect, an aging and healing effect in the form of a decrease in the decomposition rate with storage

time at room temperature is observed [102, 621]. Sample impurities, and as little as 0.04 mass-% copper(II) chloride, significantly accelerated the decomposition but did not alter the nucleation process or the rate-determining step. It was suggested that catalysis occurs through the formation of ammino complexes which tie up the ammonia on the crystal surface and thereby prevent the reversal of the proton transfer reaction.

In reviewing the Keenan and Siegmund [621] data, it was again concluded that proton transfer leads to the formation of a copper ammino complex and that the reaction of this complex with HClO_4 is the driving force of the reaction. Measurements of the catalyzed AP decomposition using small amounts of copper (0.013 to 0.2 mass-% copper (II) chloride) showed that the rate of reaction doubled with the addition of 0.04 mass-% CuCl_2 . However, the addition of further CuCl_2 caused little further catalysis [622]. These results could not be explained by previous mechanisms. It was suggested that the catalysis results from the formation of a copper-ammine complex, which is more reactive than the uncomplexed ammonia. The complexed ammonia reacts three times faster than the uncomplexed ammonia.

4.6.8.5 The Effect of Metal Chlorates and Chlorate Ion on AP Thermal Decomposition

Chlorate ions are potential contaminants invariably introduced during the production of AP. Chlorates may also form during partial decomposition of AP. They have a strong influence on the thermal stability of AP. As such, the allowable chlorate content is controlled using material specifications (see Section 4.2.2). Chlorates must never be mixed with ammonium salts in propellant or pyrotechnic formulations. Chlorate contamination in AP have been the cause of numerous accidents with pyrotechnic devices in display fireworks.

The impact of adding potassium chlorate on the thermal stability of AP is evident from a rapidly decreasing onset of the first exotherm of AP decomposition (see Table 16) [623]. The phase change endotherm remained unchanged at 517 K throughout this experiment series.

It is very dangerous to mix ammonium salts with chlorates because ammonium chlorate is very unstable and may render the mixture more sensitive to accidental ignition.

There is no practical application for ammonium chlorate and there is no interest in it other than the nuisance of it showing up as a contaminant or intermediate in AP. Nevertheless, samples of ammonium chlorate have been prepared and tested for stability [624]. Ammonium chlorate was prepared via a metathetical reaction of barium chlorate and ammonium sulfate. The barium sulfate precipitate was removed. The slow evaporation of water under vacuum and recrystallization from ethanol was not stable at room temperature but decomposed to form chlorine, nitrogen, water, and ammonium nitrate. It could be stored at 268 K (-5°C) for a longer time. Two decomposition processes were identified when performing the decomposition under carefully

Table 16: Impact of potassium chlorate addition on the thermal stability of AP.

Potassium chlorate, Mass-%	Onset of exotherms	
	K	°C
0	673	400
0.001	593, 673	320, 400
0.009	583, 673	310, 400
0.040	573, 673	300, 400
0.082	543, 673	270, 400
0.370	533	260
0.870	523	250

Data source: [623].

controlled conditions in the range of 348 and 393 K. One leads to OClO and ammonia and the other one leads to chlorine, nitrogen, water, and ammonium nitrate.

The decomposition of ammonium chlorate was studied by measuring the pressure of non-condensable gases formed and by measuring the weight lost during TGA [625]. Both methods resulted in almost identical decomposition/time curves. A measurable decomposition started at 323 K (50 °C) but some samples decomposed at 268 K (−5 °C). Explosions of fresh samples occurred at 363 K (90 °C). The reaction was autocatalytic in character and the activation energy, calculated from the slopes of time lag and rate constant against $1/T$, was 92 to 105 kJ/mol (22 to 25 kcal/mol). A similar value for the activation energy was found from the temperature dependence of the induction period before explosion. It was observed that the addition of chloric acid to ammonium chlorate considerably increased the rate of decomposition whilst the addition of ammonia had a stabilizing effect.

The topokinetical aspects of the LTD of AP crystals, i.e., the nucleation rate (V_n), the rate of nuclei growth (V_g) and their dependence on the concentration of some contaminants and temperature, have been investigated [626]. On the basis of experimental data obtained, it was inferred that the nucleation rate of the LTD for chemically pure AP is determined by the content of free protons and unavoidable ClO_3^- ion impurity

$$V_n = k[\text{H}^+][\text{ClO}_3^-]$$

and has an activation energy of $E_n = 293 \pm 16.7$ kJ/mol (70 ± 4 kcal/mol). The length of the induction period of nucleation (τ_n) is a function of the ClO_3^- contamination:

$$\tau_n = \tau_0 - A \log[\text{ClO}_3^-]$$

The corresponding value of the effective activation energy is $E_\tau = 92 \pm 20.9$ kJ/mol (22 ± 5 kcal/mol). The addition of proton donors catalyzed the nucleation process; proton acceptors inhibited it but all the proton active additives insignificantly influenced the value of V_g . The active centers were found to contain ammonium

chlorate and some amounts of AP degradation products. Several centers joined into larger centers. The activation energy for nucleation was determined as being about 293 kJ/mol (70 kcal/mol) for high purity AP and about 209 kJ/mol (50 kcal/mol) for chemically doped AP. The rate of AP decomposition products formation increased as active centers grew to larger sizes. Increased concentration of chlorate ion in AP produced a proliferation of active centers and decreased induction time before the AP LTD process started. Changes in induction time reduction and increases in the rate of AP LTD reactions were chlorate ion concentration-dependent. As chlorate content was increased, decomposition reaction rates were much greater. After recrystallizing high purity AP five times, the investigators came to the conclusion that consolidated crystalline AP is fundamentally unstable with respect to always producing a minute amount of ammonium chlorate impurity. At the lowest chlorate content in the recrystallized AP, migrating nuclei and active center growth at low concentrations could still be observed even though chemical analysis methods were unable to detect any chlorate content. During UV irradiation of AP crystals through an opaque stencil, a latent photographic image of the stencil was imprinted into the AP crystal. In the early stages of the LTD, this image may be developed and become visible. It is supposed that the latent image arises due to the generation of photo-induced ClO_3^- ions in the course of UV irradiation.

Nobody intends on using ammonium chlorate or ammonium nitrite as rocket propellants, but because of their presence as contaminants in AP and AN, their combustion mechanism and kinetics of thermal decomposition have been investigated [627]. The leading reactions of combustion of both NH_4ClO_3 and NH_4NO_2 at low pressures have been shown to proceed in the condensed phase, with the burning rate defined by the decomposition kinetics at the surface temperature. The kinetics of NH_4ClO_3 and NH_4NO_2 decomposition can be calculated using a condensed-phase combustion model. The heat effect of the decomposition reaction of solid NH_4ClO_3 to oxygen, water vapor, and HCl (or chlorine) averages 42.5–49 kcal/mol or 419–482 cal/g, depending on product composition. The enthalpy of formation of solid NH_4ClO_3 is -272.4 kJ/mol (-65.1 kcal/mol).

4.6.8.6 The Effect of Metal Perchlorates on AP Thermal Decomposition

If one wants to study the effect of metal cations on AP decomposition, the metals have to be added in the form of their perchlorates in order to eliminate interfering effects caused by the accompanying anions other than perchlorate. AP with 1 mass-% of lithium perchlorate added can survive being heated at 544 K (270 °C) for up to 24 hours without any noticeable indication of thermal decomposition. Eutectic formation in the AP/ LiClO_4 system has been credited with a stabilizing effect that extends the range of thermal stability of AP [104].

Cadmium perchlorate and silver perchlorate [628] accelerate the decomposition of AP. These are not transition metals and do not change their valency as readily as manganese or chromium. It was suggested that their activity is due to their ability to

form ammino complexes, thus removing ammonia from the AP dissociation equilibrium.

The DTA of AP/metal perchlorate samples of AP mixed with metal perchlorates in either 95/5 or 99/1 molar ratio was used in search of catalysts that did not introduce another anion [629, 630]. AP and doped AP samples were heated at various rates over a given temperature range. The perchlorates used for doping the AP were those of copper, lead, potassium, cadmium, zinc, manganese, silver, barium, magnesium (magnesium perchlorate has a very high affinity to water and is often used as a desiccating agent [Anhydron] instead of phosphorus pentoxide), sodium, and iron.

The addition of CdO to AP increased the rate and extent of its slow decomposition and lowered its ignition temperature by about 453 K (180 °C) [513]. The activation energy of the catalytic decomposition was about 121 kJ/mol (29 kcal/mol), corresponding to the activation energy expected for an electron-transfer mechanism. The rate-accelerating effect of CdO can be explained by its reaction with AP to form cadmium perchlorate, which proved to be a very active additive. In the presence of $\text{Cd}(\text{ClO}_4)_2$, AP decomposed completely below 513 K (240 °C) and it exploded at 530 K (257 °C). The activation energy of the slow decomposition and of the reaction leading to the explosion was about 123 kJ/mol (29.5 kcal/mol). The observed rate acceleration was attributed to the fusion of the AP and to the high polarizing (complex-forming) power of the cadmium ion in comparison to the effect of the less active perchlorates of magnesium, zinc, and lithium.

Doping with divalent cations of calcium does not inhibit the thermal decomposition of AP. Rather, it accelerates it [455].

Perchlorates of iron, nickel, and cobalt at 0.1 to 0.9 mass-% additive were co-crystallized with AP, dried, pulverized, and tested in the DTA and TGA [631]. Cobalt perchlorate was the most active additive of the three salts. Incorporating additives in the AP crystal lattice promotes AP decomposition more effectively than if the same compound was mechanically mixed with the AP. Metal chelates are more effective than the same metal in their oxide form. It was suggested that the metal APs decompose to the metal oxides, which then become the catalytically active part. This was supposed to be supported by the observation that when 1% metal oxides instead of the metal perchlorates were added to AP, the catalytic effects were very similar. However, other investigators showed that metal oxides become converted to metal perchlorates in the AP condensed phase. If any metal oxides form as the result of metal perchlorate decomposition, this would only be possible in the flame front where they are suspended in a gas phase.

Zinc perchlorate has only a modest effect on the thermal decomposition and ignition of AP [632].

DSC measurements of the thermal decomposition of magnesium perchlorate, AP, and a mixture of AP with magnesium perchlorate, revealed that the addition of magnesium perchlorate lowers the onset of exotherms of AP decomposition significantly and that the decomposition proceeds in a molten phase [633, 634].

DSC thermograms of the pure perchlorates by themselves under 1 atm nitrogen atmosphere prior to mixing showed the usual phase change endotherm for pure AP, followed by a low-temperature and a high-temperature exotherm for AP decomposition. The thermogram of magnesium perchlorate hydrate revealed a succession of endotherms due to the removal of water. However, it does not decompose until the temperature reaches 683 K (410 °C). The tests should have been conducted with anhydrous magnesium perchlorate instead of the hydrate.

Co-crystallization of AP with KClO_4 , and maybe a small amount of KMnO_4 , was expected to improve the thermal stability of AP [635]. The benefit of adding AN seems very dubious and would be expected to have the opposite effect.

The thermal stability and autoignition temperature of ammino complexes of transition metal perchlorates of Co, Cu, Mn, Ni, and Fe and their mixtures with AP in a 1:10 ratio were studied using DTA at 12°/min. [636]. The ignition temperatures were compared with literature values for the corresponding 1:10 metal oxide-AP mixtures. Close agreement was found between the ammino metal perchlorate complex-AP and metal oxide-AP ignition temperatures, but those of the metal ammino perchlorates alone were lower. All the ammino complexes seem to catalyze the decomposition of AP at ≤ 300 °C. The catalytic activity of the oxides may be due to the formation of metal- NH_3 complexes that facilitate proton transfer and/or explosive decomposition of the complexes, liberating heat that catalyzes the AP decomposition. Although the ignition temperatures are similar, the metal oxide-containing mixtures decomposed with greater violence than the other mixtures, indicating that both factors play a role in the catalysis.

The preparation and thermal decomposition of lithium perchlorate ammoniate $\text{LiClO}_4 \cdot 3\text{NH}_3$ and magnesium perchlorate ammoniate $\text{Mg}(\text{ClO}_4)_2 \cdot 7\text{NH}_3$ and the catalytic effect of these compounds on AP decomposition have been investigated [637]. One hesitates to call these compounds [ammino complexes]. Ammino complexes are typically formed by transition metals and the ligands are firmly held in the complex sphere. In the case of lithium and magnesium perchlorate, these compounds should be called ammoniates in analogy to hydrates. The catalytic effect of metal perchlorates on AP decomposition has been attributed to the intermediate formation of metal perchlorate ammino complexes. In the case of a Mg salt-AP mixture, the melting of the Mg perchlorate ammoniate intermediate seems to play an important role in catalyzing the decomposition.

Thermal decomposition and combustion of lithium perchlorate ammoniate/AP ($\text{LiClO}_4 \cdot 3\text{NH}_3 = \text{LPA}$) and magnesium perchlorate ammoniate/AP ($\text{MPA} = \text{Mg}(\text{ClO}_4)_2 \cdot 7\text{NH}_3$) pellets was studied using DTA, TGA, and strand burner techniques at 7.09 MPa (70 atm) [638]. The DTA results of the ammoniate/AP pellets showed that the addition of some ammoniates lowers the ignition temperature of AP. However, isothermal TG of the ammoniate/AP pellets showed that in the case of LPA/AP pellets, the extent of decomposition increased with the increase in the concentration of LPA, whereas in the case of MPA/AP pellets the extent of decomposition decreased with

the increase in the concentration of MPA. Only two LPA/AP pellets (1:10 and 1:20) had higher burning rates compared to plain AP pellets. On the other hand, MPA/AP pellets had lower burning rates compared to AP pellets and some extinguished. Increasing the concentration of MPA in MPA:AP pellets completely suppressed combustion. MgO suppressed AP combustion once its concentration exceeded 5%.

As evident from DTA and TGA data, the addition of Cu^{2+} , Mn^{2+} , Co^{2+} , or Fe^{3+} affects the rate of decomposition due to lattice modification and the formation of catalytically active oxides during decomposition [639]. Small concentrations of these ions inhibited the decomposition by eliminating the first exothermic peak. At higher concentrations, a catalyzed decomposition was observed. Either the influence of the doping ions on the mechanism of the thermal decomposition is different from that of added oxides or a modification of the electron transfer mechanism is taking place.

Doping of AP with Ba^{2+} ions instead of Mg^{2+} ions can have opposite effects depending on the temperature range [464]. The catalytic effectiveness of metal perchlorates is related to the polarizing power of the cation. Also, lowering the melting point will accelerate decomposition because the addition of other salts of the same cation (but with higher melting points) does not show any catalytic effects.

4.6.8.7 The Effect of Metal Fluorides on AP Thermal Decomposition

While the addition of fluorides to metallized solid propellants can potentially increase burning rates, only minute effects were observed when various fluorides were added to uncatalyzed, non-metallized AP [640]. DTA and isothermal TGA were used to study the effect of the addition of ~10% LiF, NaF, MgF_2 , and NH_4F on AP thermal decomposition. With LiF, the DTA of AP remained unchanged. However, isothermal TGA at >543 K (>270 °C) showed some decomposition to ~25% weight loss. With NaF and MgF_2 , the isothermal TGA showed no change but at 578 K (305 °C) NH_4F appears to have some catalytic effect. The lack of effect of LiF at 543 K (270 °C) may be due to the formation of NH_4F and its volatilization. Other observers claimed that LiF can stabilize AP similar to LiClO_4 . Interacting with AP, it forms lithium perchlorate, which inhibits subsequent decomposition [104].

Fluorides of transition metals act as catalysts in the thermal decomposition of AP at 503 K (230 °C). The catalytic activity of fluorides decreased in the order of: $\text{Co}^{2+} > \text{Mn}^{2+} > \text{Zn}^{2+} > \text{Cu}^{2+} > \text{Ni}^{2+}$. When all other conditions were kept the same, it was always lower than the catalytic activity of the corresponding oxides [641].

4.6.8.8 The Effect of Other Anions on AP Thermal Decomposition

Many investigators studied the catalytic activity of other metal salts (other than oxides) in comparison to that of the metal oxides. It was generally found that the anion does not nearly have as much of an effect on AP decomposition as the cation.

Metal salts of anions that are readily decomposing at the temperature of AP decomposition, such as oxalates or carbonates, are likely to result in the formation of finely divided metal oxides. These are freshly formed and had higher activities than metal oxides that were added as bulk powders.

Effects of Oxalates on AP Thermal Decomposition

When ClO_4^- was partially replaced by $(\text{COO})_2^-$ in a 10^{-1} mol ratio and tested in the TGA, pure AP showed 50% decomposition at 681 K (408 °C) and 100% at 720 K (447 °C). However, the doped sample showed 50% decomposition at lower temperatures (50% at 677 K/404 °C) and 100% at 712 K (439 °C) [642].

The effect of CoC_2O_4 on the catalytic thermal decomposition of AP was measured by DSC and TG-MS. It was found that freshly formed nano-cobalt oxides exhibited better catalytic performance in the thermal decomposition of AP than bulk CoO [643, 644]. Adding 2% of CoC_2O_4 to AP decreased the decomposition temperature by 104 °C and increased the heat of decomposition from 655 J/g to 1469 J/g. Some oxidation of adsorbed ammonia by cobalt oxides via the superoxide active centers took place on the surface of the cobalt oxide. The presence of oxygen can accelerate the oxidation thermal decomposition process of AP, with a distinct increase in the DSC rate of heat release being seen.

The effect of cobalt oxalate nanocrystal morphology on the thermal decomposition of AP was examined using DSC [645]. No direct relationship between the morphologies of catalysts and their activities was observed.

Effects of Carbonates on AP Thermal Decomposition

The kinetics of thermal decomposition of AP in the presence of basic Cu carbonate and Cr carbonate catalysts were studied by isothermal TGA [646]. Prout-Tompkins and contracting-cube equations were found to fit the isothermal TGA data of the catalyzed decomposition. The reaction mechanism was discussed in light of the postulated electron transfer process [647].

Effects of Anions Other Than Oxalate or Carbonate on AP Thermal Decomposition

The addition of 1 mol-% of $\text{Cu}(\text{ClO}_4)_2$, AgClO_4 , or NH_4I prior to irradiation using X-rays or γ -rays lowered the thermal stability of AP and enhanced the effects of irradiation [648]. The thermograms of samples containing one mol-% of Cu^{2+} ion, irradiated and unirradiated, exhibited sharp exotherms immediately following a crystalline transition at 543 K (270 °C). The same peak was also enhanced as a result of exposure to X-rays and γ -radiation. Irradiated samples containing Cu^{2+} ion had an exotherm at 509 K (236 °C). These results may be explained in terms of an electron transfer. The DTA thermogram for the irradiated sample containing iodide was similar to that of AP not containing this impurity. Some of the iodide became oxidized and escaped from the sample in the form of elemental iodine.

A TGA study of the thermal decomposition of AP at 487 to 743 K (214 to 470 °C) in air produced the following values of the energies of activation for AP by itself [649]:

Orthorhombic form:	$E_{\text{act}} = 167.4 \text{ kJ/mol (40 kcal/mol)}$
Cubic form:	$E_{\text{act}} = 100.4 \text{ to } 117 \text{ kJ/mol (24 to 28 kcal/mol)}$
Residue from low-temperature reactions	$E_{\text{act}} = 150 \text{ to } 163 \text{ kJ/mol (36 to 39 kcal/mol)}$

The study of the effect of oxides, chlorides, carbonates, and oxalates of a number of metals on the thermal decomposition of AP showed that the compounds of manganese and cobalt lead to complete decomposition of AP at temperatures below 513 K (240 °C). The compounds of iron, nickel, and chromium lead to the complete decomposition of AP at slightly higher temperatures, namely 543 to 553 K (270 to 280 °C). At the same temperature, the maximum rate of decomposition of AP with additives of the compounds of Cu, Mn, Co, as well as ZnO, was greater than the maximum decomposition rate of the pure AP. However, on the other hand, the maximum decomposition rate of mixtures of AP with compounds of iron(?), nickel(II), chromium(III), as well as V_2O_5 was less than for pure AP. The activity of additives of the same element decreased in the following order: carbonate (oxalate), oxide, chloride. The inhibiting effects of iron is more than surprising since all other investigators found iron compounds to be good catalysts for AP decomposition. AP containing 5% Cr_2O_3 did not burn at atmospheric pressure, even if it was pre-heated to 373 K.

AN or AP crystals modified by co-crystallization with isomorphously substituted catalytic salts are more sensitive to impact and have a lower decomposition temperature than pure AN or AP. While increased impact sensitivity may be undesirable for propellant applications, it makes the materials more applicable as explosives. Suitable catalytic salts are sodium chromate, lithium iodate, potassium iodate, calcium permanganate, ammonium chromate, ammonium periodate, or ammonium permanganate [650]. The catalytic effect can be measured by a decrease in the drop height (for 50% positive initiation) and weight loss in TGA. For instance, normal AP would lose 22% of weight after 15 minutes at 573 K (300 °C), whereas AP with 2% $Kmno_4$ would lose 99% after 20 minutes at 449 K (176 °C).

The easiest way to introduce stabilizers or burning rate catalysts into AP is to dissolve the AP in water, mix in the additive(s), and spray dry the solution or even the suspension if the additives are not soluble [651]. AP doped in this manner and the additives tested include ammonium dichromate as the catalyst and ammonium hydrogen phosphate as the stabilizer. The spray-dried AP particles are spherical and 5 to 20 μm in diameter.

The role of silver in promoting the thermal decomposition of AP has repeatedly been studied. It was shown that silver metal and silver chloride reduce the induction period of the LTD of AP and somewhat increased the rate of subsequent reactions [512]. The catalytic effects of silver nitrate and silver oxide were significantly greater than those of $AgCl$. Microscopic observations provided strong evidence that these reactions proceed with local and incomplete melt formation around clusters of additive. It was also shown that the complex salt $[Ag(NH_3)_2]ClO_4$ melts below the onset temperature of reaction and that it promotes AP decomposition, which is usually accompanied by melting. The activity of these silver salts in promoting AP breakdown is a consequence of local reactant fusion. The chemistry of the reactions in these melts is complicated because it involves several participants, including the complex ion $[Ag(NH_3)_2]^+$. Silver catalysis is most effective during the first phase of decomposition. Deactivated silver-

containing compounds accumulate on the outer eroded surface of the AP crystal. The nuclei continue to advance into the remaining undecomposed AP.

The mechanism of thermal decomposition of orthorhombic AP, though studied extensively in the past, still remains controversial. Proton transfer has been proposed as the rate-determining step by some authors, whereas others have inferred the occurrence of electron transfer. More experimental evidence was sought to help clarify this controversy. The isothermal decomposition of orthorhombic AP was studied as a function of the concentration of anionic dopants, sulfate SO_4^{2-} and phosphate PO_4^{3-} [652]. In either case, the rate of decomposition passed through a maximum as the dopant concentration increased. The activation energy of the decomposition process remained unaltered by doping. The results were interpreted as supporting the theory of an electron transfer mechanism.

The proton transfer mechanism has been supported by Boldyrev et al. based on their observation that AP doped with SO_4^{2-} (concentration: 0.889×10^{-2} mol % in solution) or PO_4^{3-} (concentration: 1.181×10^{-2} mol % in solution) exhibited a decrease in the decomposition rate [425]. However, Maycock, and Verneker found that AP doped with SO_4^{2-} had an increase in the rate up to a dopant concentration of 1.0×10^{-2} mol % (in solution), and that the rate decreased if the dopant concentration was increased beyond a maximum concentration [653].

The thermal decomposition of AP has usually been described in terms of chemical reactions with the point defect structure of the solid ignored. Both the isothermal and adiabatic decompositions have been reinvestigated over the temperature range of 473 to 723 K (200 to 450 °C). There is a good correlation between the isothermal d.c. electrical conductance of single crystals, and of conductance as a function of temperature with the extent of decomposition, indicating that electric charge carriers play a significant role in the thermal decomposition of AP [153]. The study of the electrical conductivity as a function of temperature has resulted in the assignment of a probable defect structure to AP. It is likely to have cationic Frenkel type defects below 523 K (250 °C) and Schottky disorder at higher temperatures. This suggests an explanation for the phenomenon of only 30% decomposition below 523 K (250 °C) and 100% above this temperature. The decomposition is very dependent on lattice defects in the crystals. Bivalent foreign anions in the crystal lattice will produce additional anion vacancies. Freshly ground and aged pulverized AP may produce different decomposition behaviors because some of the defects will heal with time. Therefore, when carrying out AP decomposition studies with pulverized samples, it is necessary to use samples of the same age.

These contradictions required a systematic study of the decomposition of AP as a function of SO_4^{2-} content. Similar behavior is to be expected for AP doped with PO_4^{3-} . The thermal decomposition of phosphate-doped AP has not been studied as yet as a function of dopant concentration. The Kannan [652] paper dealt with the isothermal decomposition of sulfate-doped and phosphate-doped AP in the temperature range of 200–230 °C, where AP exists in its orthorhombic modification.

The substitution of NH_4^+ or ClO_4^- by aliovalent ions increases the defects in the crystal lattice and will cause AP to decompose at a lower temperature, possibly increasing the burning rates of solid propellants prepared with doped AP. Thus, the reaction rate of AP measured using a vacuum stability test or TGA was reduced by the partial substitution of NH_4^+ ions by Ca^{++} ions in a 10^{-2} mol ratio by heating a mixture of 10 g AP, 100 mg $\text{Ca}(\text{NO}_3)_2$, and 25 mL H_2O to 363 K (90 °C). Cooling to room temperature then followed, with subsequent drying of the recovered co-crystallized precipitate [642]. In the vacuum stability test at 498 K (225 °C), oxygen evolution from AP increased the pressure from 50 to 100 μm Hg in ten minutes but the doped sample took longer, taking 24 minutes to reach the same pressure. At 523 K (250 °C), the same pressure increase occurred in 2 and 4 minutes, respectively.

The rate of the bulk decomposition reaction of AP was enhanced in both Ba^{2+} and SO_4^{2-} doped crystals [159]. Whereas Ba^{2+} shortened the time to completion of the surface reaction, doping with SO_4^{2-} prolonged it. This was interpreted as supporting the theory of a step-wise proton transfer mechanism with the participation of crystal lattice defects.

The low-temperature thermal decomposition of AP was found to be initiated by a single-stage nucleation process at a lattice defect site on the surface of the crystal [621]. Crystals that are aged at room temperature revealed a decrease in the decomposition rate with storage time. It appears that aging allows the slow repair of crystal defects. Sample impurities and as little as 0.04% copper(II) chloride significantly accelerated the decomposition but did not alter the nucleation process or the rate-determining step. Decomposition was measured using a gasometric method. The addition of 0.2% CuCl_2 increased the rate of gas evolution from 2.05 mL/min. for pure AP with 0% CuCl_2 to 5.92 mL/min. with 0.2% CuCl_2 . The reaction stoichiometry was altered by CuCl_2 addition but not by recrystallization. Some samples were recrystallized as often as four times but there was no change in the decomposition behavior. It was suggested that catalysis occurs through the formation of ammino complexes, which tie up the ammonia on the crystal surface and thereby prevent the reversal of the proton transfer reaction.

4.6.8.9 The Effect of Organic Cations on AP Thermal Decomposition

Guanidinium perchlorate forms a eutectic with AP at 9 mol-% AP, which melts at 490 K (217 °C) [654]. The thermal stability of an 80 mass-% AP/20% guanidinium perchlorate mixture was studied using TGA in the temperature range of 523–553 K (250–280 °C) [654]. After a lengthy induction period, the process begins to accelerate rapidly. It would have been of interest to measure strand burning rates of eutectic crystals and other AP/guanidinium perchlorate mixtures.

DTA and TGA of AP doped with mixed or co-crystallized tetramethylammonium perchlorate (TeMAP) showed that the thermal decomposition of AP is considerably modified when it is mixed or co-crystallized with TeMAP [655]. The DTA of AP usually revealed an endotherm at 513 K (240 °C) due to phase transformation which remained

unchanged when AP was co-crystallized or mixed with TeMAP. The DTA of AP co-crystallized or mixed with 1 mol-% TeMAP revealed only one exotherm corresponding to the complete decomposition. Whereas in the case of the physically mixed sample the exotherm occurred at 623 K (350 °C), the co-crystallized sample with the same TeMAP concentration decomposed completely at 558 K (285 °C). The decomposition of an AP-based propellant revealed considerable desensitization when AP + 1 mol-% TeMAP was used as the oxidizer.

In comparison to similar effects with AP, the addition of trimethylammonium perchlorate to potassium perchlorate catalyzed its thermal decomposition [656]. However, although the additive sensitized the potassium perchlorate/polyurethane (PU) propellant thermal decomposition, its combustion was desensitized. The observed effects have been explained in terms of the role played by the early formation of finely divided potassium chloride.

Because the four MEAP have such a dissimilar effect on the burning rate and thermal stability of AP, the heat of combustion of mono-, di-, tri-, and TeMAP were determined by bomb calorimetry [657]. The data was used to explain why the thermal behavior of AP is considerably modified in the presence of these compounds as shown by DTA or DSC. Above a particular concentration of MAP, AP ignites in a single step around 563 K (290 °C). The minimum concentration of any of the four MEAP (mono-, di-, tri- or tetra-methylammonium perchlorate) needed to cause AP ignition in a single step depends on the intramolecular elemental stoichiometric coefficient of the mixtures. These have the same values regardless of which MEAP is used. It was found that the calorimetric values of these mixtures are the same. The heat evolved upon combustion of such a composition seems to determine the lower concentration limit of combustion at ambient pressure.

The effect of tetrabutylammonium perchlorate (TBAP) on the thermal decomposition of AP has been studied using DSC experiments with a heating rate of 5°/min. with oxidizer-rich, stoichiometric, and fuel-rich compositions [658]. The onset of the decomposition temperature of pure TBAP was very similar to that of the first-stage decomposition of AP, 538 K (265 °C) compared to 542 K (269 °C) for AP. Even though TBAP's decomposition began close to that of AP, its peak decomposition rate was achieved around the temperature at which AP's first-stage decomposition ended. When changing the AP/TBAP composition from an oxidizer-rich system to a fuel-rich system, the temperature of inception of the first-stage decomposition began decreasing, while the temperature of peak decomposition rate and the temperature of completion of decomposition shifted towards a higher temperature regime.

4.6.8.10 The Effect of Metalorganic Compounds on AP Thermal Decomposition

The advantage of metalorganic compounds as burning rate additives is that they are miscible with the binders and can be placed at the surface of AP grains where they are needed the most. The disadvantage of metalorganic burning rate catalysts like ferrocene or metal acetylacetonates is that they are volatile and tend to migrate during

the aging of the propellant. It is thus of interest to study not only the effect of metalorganic additives on the burning rate of formulated propellants but also their effect on the thermal decomposition of AP itself.

Effects of Metallocenes on AP Thermal Decomposition

The effect of metallocenes on the thermal stability of AP and the burning rate of AP-based propellants can be examined at several stages: (1) with AP by itself without the addition of a fuel, (2) with AP in combination with a fuel, or (3) in a completely formulated propellant containing AP, binder, and often a metal powder also.

Solid Fe_2O_3 is the conventional combustion catalyst for AP/HTPB (NH_4ClO_4 /hydroxyl-terminated polybutadiene) type propellants. The catalytic effects of three different liquid ferrocenes (butylferrocene, dimethylferrocene, and dibutylferrocene) were compared to that of Fe_2O_3 as reference material [659]. The comparison for catalytic activity was based on DTA and TGA measurements.

Not all ferrocenes are compatible with AP and some may cause unwanted premature reactions. The effect of the presence of iron-containing compounds on the thermal decomposition of AP was studied using DTA and TGA. The maximum decomposition reaction temperature I of AP was lowered in the presence of iron-containing ("ferruginous") compounds. It is then shifted to lower temperatures as the additive concentration is increased [660]. The temperature lowering ability of catocene [2,2-bis(ethylidicyclopentadienyl-iron) propane] on the thermal decomposition of AP is more efficient than that of two other iron-containing compounds previously investigated. The decomposition mechanism of small particle size AP powder differs from that of coarse particle size AP.

The thermal decomposition of AP with and without ferrocene derivatives was studied using DTA and DSC-TGA [661]. The results indicated that reducing AP particle size or increasing the content of ferrocene derivatives can shorten the gap between high-temperature thermal decomposition peaks of AP and low-temperature thermal decomposition peak of AP. It can also enhance the low-temperature thermal decomposition rate of AP. In the presence of AP, the side-chain of ferrocene derivatives is easily ruptured and the residual main skeleton, ferrocene or ferrocene ion, is the real catalyst in the thermal decomposition of AP. Ferrocene derivatives inhibit proton transfer processes of AP but they are strong catalysts for the decomposition of HClO_4 , one of the initial decomposition products of AP.

The effect of catocene on the thermal decomposition of AP as an oxidizer in composite solid propellants was studied using XPS [662]. Results revealed that the bond energy of iron increased after thermal oxidation. Catocene was oxidized during the thermal decomposition of AP. Fe—C conjugate bonds were broken gradually, according to the spectral intensity change of the $\text{Fe}^{2p^{3/2}}$ peak. The binding energy of chlorine decreased and low binding energy peaks appeared at about 200 eV. The intensity of those peaks increased gradually. The possible explanation for forming a binding state of chlorine at about 200 eV was that catocene decomposed to cyclopentadiene ion,

which then reacted with HClO_4 resulting in the formation of HCl and the accelerated decomposition rate of HClO_4 . The ferrocene-based sandwich structure of catocene was destroyed and Fe was oxidized to form Fe_2O_3 , which is an active catalyst that could also accelerate the decomposition rate of HClO_4 , a dissociation product of AP.

The thermal decomposition of AP and AP/Catocene mixtures was studied using DSC and TGA. The activation energy and the pre-exponential factor was calculated [663]. In the DSC thermogram, there was an additional exothermic peak at 180°C with Catocene, which belongs to the decomposition of Catocene. The activation energy for low- and HTD reactions of AP decreased by 13.2 kJ/mol and 7.1 kJ/mol , respectively, as a result of the addition of catocene.

Simultaneous TGA/DSC-FTIR was employed to study the effect of catocene at high concentrations (5, 15, and 25%) on the thermal decomposition of AP with different particle sizes [664]. The results showed that catocene has an effect on the thermal decomposition of AP. However, the role that catocene played changed with the concentration of catocene and the particle size of AP. High concentrations of catocene (more than 15%) accelerated the decomposition of fine AP at low temperatures but had little effect on the decomposition of the median and coarse AP.

Effects of Metal Acetylacetonates on AP Thermal Decomposition

It is of interest to study not only the effect of metal acetylacetonates (β -diketonates) on the burning rate of formulated propellants but also their effect on the thermal decomposition of AP itself [665].

Effects of Metal Carboxylates on AP Thermal Decomposition

Metal soaps (metal alkylcarboxylates) have been used for a long time as burning rate catalysts and emulsifiers for solid propellants. Many of these metal carboxylates will decompose to finely distributed metal oxides under conditions of the rocket motor.

DSC and TGA-MS catalytic activity measurements were carried out on the catalytic thermal decomposition of AP over CoC_2O_4 [643]. The results showed that nano-cobalt oxides formed during decomposition are active catalysts in the thermal decomposition of AP. Adding 2% of CoC_2O_4 to AP decreased the onset of decomposition temperature by 104°C and increased the heat of decomposition from 655 J/g to 1469 J/g . The oxidation of adsorbed ammonia by cobalt oxides via the superoxide active centers takes place on the surface of cobalt oxide. The presence of oxygen can accelerate the oxidation thermal decomposition process of AP, with a clear increase in DSC heat release.

Effects of Other Metalorganic Compounds on AP Thermal Decomposition

While there is a widespread trend to avoid lead compounds as burning rate modifiers in any propellant, some of the less common lead organic compounds are still being tested as AP decomposition catalysts but this seems to be an academic exercise in futility [666].

The effect of various metal complex catalysts of 1,4,8,11-tetraaza[14]annulenes on the thermal decomposition of AN, AP, and a solid propellant containing AP as the oxidizer was studied using DTA and burning rate measurements [667]. Iron and vanadium catalysts had high activity during the thermal decomposition of AP and an AP-based solid propellant. For the solid propellants, which contained iron or vanadium complexes as catalysts, the burning rate increased by 1.6 times and their pressure index decreased to 80% compared to the burning experiments without a catalyst at a pressure of 5.0 MPa (see [668]).

4.6.8.11 The Effect of Nano-Metals on AP Thermal Decomposition

Nano-metals are added to AP-based propellants for several reasons: The main objective would be to increase the specific impulse by choosing metals with high heats of combustion and to achieve more complete combustion of the metal (see Section 5.18). Another reason would be to add metals that catalyze the thermal decomposition of AP and thus increase the burning rate. There were big expectations for propellant improvements when using nano-metals instead of micron-size metals, however, only time will tell if the hype about nanomaterials in the late 1990s was justified.

Cu and NiCu nano-powders decreased both the higher and lower decomposition temperature of AP while Ni and Al nano-powders just decreased the higher decomposition temperature and increased the lower decomposition temperature [669]. Coarser, micron-sized metal powders had some catalytic effects on the thermal decomposition of AP but their effects were less than that of nanometer metal powders. Increasing the nano-metal content enhanced their catalytic effect on the HTD of AP, however, their effect on the LTD was less pronounced (see [670]).

A study of the decomposition behavior of AP in the presence of Cu nano-powder using DTA revealed that nanometer Cu powder decreased the first and second thermal onset of decomposition temperatures of AP by 35° and 130°, respectively. Additionally, the DTA heat release of AP in the presence of Cu nano-powders increased to 1.20 kJ/g [671]. The catalytic effect of Cu micron-size powder on the thermal decomposition of AP was less than that of Cu nano-powder. Increased Cu nano-powder concentrations enhanced its catalytic effect on the HTD of AP but weakened its catalytic effect on the LTD of AP. It was suggested that metal oxides act as intermediates in the process of electron transfer. Cu nano-powder reacts with the decomposition products of AP and has a special surface effect.

Three types of nanometer transition metals (Ni, Cu, and Co) were prepared from an aqueous solution by reducing their corresponding metal salts. Their catalytic activity on the thermal decomposition of AP was measured using DTA [672]. Results indicated that the catalysis of nanometer Ni and Cu increased with the content of nano-metals. Moreover, the high- and low-temperature AP decomposition peaks have a tendency of overlapping with each other. A suitable content of nano-metal Co powder in the composite is about 5%. The catalysis of nano-metal Co results in the lowest thermal

decomposition temperature of AP. The catalytic capability of nanometer transition metals can be correlated with the stabilization energy of their formed ammino complexes. Such complexes have been postulated as intermediates in the decomposition of AP.

A DTA study of the catalytic effect of Zn nano-powders and micro-powders on the thermal decomposition of AP revealed that both sizes of Zn powders have a similar catalytic effect on the decomposition of AP. The total heat releases of AP catalyzed by Zn nano-powders were generally higher than those of AP mixed with Zn micro-powders [673].

A magnesium-copper alloy can not only be used for hydrogen storage but can also be used to catalyze AP decomposition [674]. Co, Ni, and Ni-P nanoparticles can be pyrophoric in air and are also catalysts for AP decomposition [675, 676].

Ni particles in Ni/TiO₂ nanoparticles exhibit better dispersion. Additionally, the size of most Ni particles is of the order of 10 nm. The catalytic activity of Ni/TiO₂ nanoparticles on the thermal decomposition of AP was investigated using simultaneous TGA and DTA [677]. The improvement of catalytic activity can mainly be attributed to the improvement of Ni dispersion in Ni/TiO₂ nanoparticles. The catalytic activity of Ni/TiO₂ nanoparticles increased by increasing the weight ratio of Ni to AP.

The catalytic activity of 10-nm Pd-B/TiO₂ on the thermal decomposition of AP was investigated using simultaneous TGA-DTA. The results showed that Pd/TiO₂ exhibits very high catalytic activity in the thermal decomposition of AP [678]. The enriched electron state of Pd active sites and high dispersion of the Pd active sites on TiO₂ support are mainly responsible for the improvement of catalytic activity of Pd/TiO₂ amorphous alloy catalysts. Palladium would be a very expensive catalyst to use and is only of academic interest.

Bimetallic nanocrystals made of Cu-Co, Cu-Fe, and Cu-Zn alloys with particle sizes of 10–38 nm can have a significant catalytic effect on the thermal decomposition of AP. They also impact on the burning rate of AP-based composite solid propellants [679]. This catalytic activity has been attributed to the large surface area and the crystal defect nature of the bimetallic nanocrystals.

Nano-metal/carbon (Metal = Fe, Co) composite materials, in which nano-iron and -cobalt particles were uniformly distributed in a carbon matrix, were prepared using pyrolysis of metal-exchanged cation exchange resins (M-PAA) [680]. XRD and TEM results revealed that the particle size and morphology of nano-iron and cobalt could be controlled using the pyrolysis temperature. The particle size of Co and Fe in M/C obtained at 773 K (500 °C) was 15–40 nm and 10–35 nm, respectively. DTA of the thermal decomposition of AP indicated that the decomposition temperature of AP lowered with the addition of M/C-500, and the HTD peaks of AP were lowered by as much as 145 °C and 68 °C by adding 5% of Co/C and Fe/C obtained at 773 K (500 °C). The high- and LTD peaks of AP overlapped with the addition of Co/C.

Transition metal nanoparticles of four of the 3d transition metal series (Cu, Co, Ni, and Fe) were prepared using hydrazine reduction of metal chlorides in ethylene glycol at 333 K (60 °C). These were then characterized using XRD [681]. The XRD pattern showed average particle sizes for Cu, Ni, Co, and Fe of the order of 17, 41, 27, and 35 nm, respectively. The activity of these transition metal nanoparticle accelerants on the thermal decomposition AP was investigated using TGA, DSC, and ignition delay measurements. Isothermal TGA data were used to evaluate the kinetic parameters by model fitting as well as isoconversional methods. The activation energy for the thermal decomposition of AP was found to be 66.8, 68.7, 78.5, and 85.4 kJ/mol, respectively, for Co, Cu, Ni, and Fe, when they were mixed with AP. Hence, the order of catalytic activity was found to be $\text{Co} > \text{Cu} > \text{Ni} > \text{Fe}$. The accelerant effect of nanoparticles of the metals themselves was found to be better than that of their respective nano-oxides.

Nano β -Cu particles were prepared via a wet mechanical grinding method and were characterized using XRD, field emission SEM, and TEM [682]. Nano β -Cu was semi-spherical and homogeneous with a fairly uniform size of 100 nm. A DSC study of the catalytic properties of nano β -Cu revealed that the nano β -Cu had significant catalytic effects on the decomposition of UFAP with different particle sizes. The peak temperature of decomposition for 6 μm and 1 μm AP decreased to 646 and 624 K (373 and 351 °C), respectively, and the apparent decomposition heat increased to 1529 and 1513 J/g, respectively. The reaction rate constant increased approximately ten times. Compared with 6 μm AP, nano β -Cu lowered the peak temperature of the HTD of 1 μm AP, and the reaction rate constant increased, indicating that nano β -Cu exhibits much better catalytic efficiency for accelerating the thermal decomposition of 1 μm AP.

Platinum is not exactly the cheapest catalyst metal to use, however, one of the reasons for investigating the effect of platinum on AP decomposition is that sometimes platinum thermocouples are used for temperature measurements and their presence may disturb the results of the experiment.

The catalytic activity of platinum nano-powders on the thermal decomposition of AP was characterized using DSC/TGA [683]. Results revealed that the addition of flower-like and dendritic Pt nanostructures decreased the high decomposition temperature of AP by 96 °C and 114 °C and increased the total DSC heat release by 1.28 and 1.36 kJ/g, respectively.

Pt- Al_2O_3 aerogels were synthesized via solution-freeze-drying-calcination technology and used catalysts to catalyze the thermal decomposition of AP [684]. The onset of the thermal decomposition temperature of AP was reduced from 691 to 620 K (418 to 347 °C) and the heat release was increased from 165 to 1784 J/g. Pt/ Al_2O_3 aerogel was a good catalyst for the thermal decomposition of AP, but who can afford it?

4.6.8.12 The Effect of Carbon on AP Thermal Decomposition

Activated charcoal and soot have a pronounced effect on the thermal decomposition of AP and are often added as a burning rate catalyst. The carbon additive in propellants acts as a fuel as well as an absorber of IR radiation. The role of carbon in composite

propellants is sometimes described as that of an “opacifier”. Other forms of carbon that have been tested as potential burning rate catalysts are C_{60} (“Buckyballs”, buckminsterfullerene) and carbon nanotubes (CNT).

Graphite is added (at least to the surface) to make the propellant more conductive to prevent the build-up of electrostatic charges leading to accidental ESD ignition.

TGA-DTG, DTA, and oxygen bomb combustion calorimetry experiments were used to evaluate the effects of carbon black, fullerene soot, extracted fullerene soot, and pure C_{60} on the thermal decomposition characteristics of AP [685]. The investigations found that fullerene soot can evidently improve the LTD of AP and increase the exothermic output and the heat of detonation of AP.

AP/CNT mixtures were prepared using three different mixing methods, namely **(1)** dry-mixing, **(2)** water-mixing, and **(3)** acetone-mixing [686]. Combustion and thermal decomposition studies of AP with CNTs showed that the burning rate of AP/CNTs mixtures increased, and pressure exponents decreased with increasing CNT content of the mix. The catalysis of CNTs on AP depends on different mixing methods. For AP/CNT mixtures prepared using methods (1) through (3), the catalytic effect, burning rate increase, and the pressure exponent decreased in the order $3 > 2 > 1$.

The effects of fullerenes, including fullerene soot, extracted fullerene soot, and pure C_{60} on the thermal decomposition of AP compared with traditional carbon black were investigated using TGA, DTA, IR, and ignition temperature experiments [687]. The results showed that the addition of fullerene soot to AP reduced the activation energy as well as the temperature at the maximum decomposition rate. However, it was found that extracted fullerene soot and pure C_{60} had little effect on the thermal decomposition of AP. Among all carbon catalysts, fullerene soot was the most active one.

Graphene has been used as a carrier for manganese sesquioxide as a catalyst for AP decomposition [547].

Three-dimensional hierarchically ordered porous carbon (3D HOPC) was used as a catalyst to improve AP thermal decomposition through synthesizing a series of AP/HOPC nanocomposites with different AP loading fractions [688]. In these nanocomposites, AP nanocrystals (26–69 nm) were space-confined into the 3D HOPC scaffold and demonstrated high catalytic activity for AP thermal decomposition in decreasing the HTD temperature from 714 to 588 K (441 to 315 °C), lowering the activation energy from 176 ± 19 kJ/mol to 131 ± 5 kJ/mol, and increasing the heat release from 371 ± 11 J/g to 3765 ± 10 J/g. Carbon-based materials are proposed as catalysts for AP-based solid propellants.

The catalytic effect of functionalized GO cross-linked with triaminoguanidine ligand and transition metal complexes on the thermal decomposition of AP or RDX was studied using DSC and SEM [689]. These compounds have a strong catalytic effect on the decomposition of AP and may even stabilize RDX crystals before they decompose due to thermolysis.

4.6.8.13 The Effect of Carbon Nitride on AP Thermal Decomposition

Graphitic carbon nitride ($g\text{-C}_3\text{N}_4$), metal-free or intercalated with transition metal oxide, has intrinsic catalytic activity for the thermal decomposition of AP. Adding 10 mass-% $g\text{-C}_3\text{N}_4$ to AP decreased the onset of decomposition temperature by 70 °C and the activation energy by 119.8 kJ/mol [690]. The apparent decomposition heat of AP in the presence of 10 mass-% $g\text{-C}_3\text{N}_4$ was 1362.6 J/g, which is much higher than that of pure AP (574.2 J/g). The unique surface structure of $g\text{-C}_3\text{N}_4$, consisting of triazine units connected by planar amino groups, favors the adsorption and diffusion of perchloric acid via Lewis acid-base interactions, which decreases the reaction activation energy of AP and facilitates the formation of superoxide radical anions (OO^-) and holes (h^+), thus enhancing the oxidation reaction of ammonia.

The catalytic activity of graphitic carbon nitride can be improved using intercalation of cerium(IV) oxide [691]. $g\text{-C}_3\text{N}_4/\text{CeO}_2$ nanocomposites were synthesized through a simple mixing-calcination method and characterized using XRD, FTIR, EDAX, TEM, and XPS, revealing that CeO_2 nanoparticles with a diameter of 50–100 nm were uniformly loaded on the surface of $g\text{-C}_3\text{N}_4$. The $g\text{-C}_3\text{N}_4/\text{CeO}_2$ nanocomposites catalyzed the thermal decomposition of AP more effectively than pure $g\text{-C}_3\text{N}_4$ or CeO_2 . The weight loss decomposition temperature of AP was decreased by up to 74.6 °C by adding $g\text{-C}_3\text{N}_4/\text{CeO}_2$ nanocomposites. There may be a synergistic effect between $g\text{-C}_3\text{N}_4$ and CeO_2 .

Similar results were obtained with mesoporous graphitic carbon nitride (mpg- C_3N_4) that was modified by the insertion of CuO nanorods [692]. Examination with TEM, SEM, XRD, FTIR, and XPS revealed that CuO nanorods (length of 200–300 nm, diameter of 10–15 nm) were uniformly dispersed throughout mpg- C_3N_4 . The weight-loss decomposition temperature of AP was decreased by up to 118 °C in the presence of 2 mass-% mpg- $\text{C}_3\text{N}_4/\text{CuO}$ nanocomposites. There may be a synergistic catalysis effect between mpg- C_3N_4 and CuO that is similar to the one observed with CeO_2 .

$g\text{-C}_3\text{N}_4/\text{CuO}$ can be prepared using a microwave-assisted method [693]. It was found that, upon adding m- $g\text{-C}_3\text{N}_4/\text{CuO}$ nanoparticles, the weight-loss decomposition temperature of AP was reduced by 136 °C, which was much more pronounced than that from adding other nanocomposites. The amount of released heat from the decomposition of AP mixed with m- $g\text{-C}_3\text{N}_4/\text{CuO}$ was seven times higher than that from pure AP.

The effect of transition-metal-doped graphitic carbon nitride (M- $g\text{-C}_3\text{N}_4$, M = Fe, Nd, Ce, Zr, U) as a catalyst for the thermal decomposition of AP and AP adducts was examined using DSC [694]. Among the tested catalysts, Fe- $g\text{-C}_3\text{N}_4$ had the best catalytic activity for the thermal decomposition of AP adducts. Fe- $g\text{-C}_3\text{N}_4$ shifted the exotherm peak temperature of AP by 75 °C, increased the heat release by 464 J/g, and decreased the activation energy by 55 kJ/mol.

4.7 Autoignition Temperature and the Ignition Delay of Ammonium Perchlorate in the Presence of Catalysts

The autoignition temperature of AP is lowered significantly and the ignition delay is shortened substantially in the presence of catalysts. Often the autoignition temperature and ignition delay of pure AP is compared to that of doped AP. Autoignition temperatures and ignition delay times of unadulterated AP have already been summarized in Table 11 in Section 4.4. Table 17 provides a summary of the autoignition temperatures and activation energies (derived from ignition delay) for catalyzed AP. Table 18 is a summary of similar data. Omitted from the latter table are data with metal oxides that were doped with traces of other metals to determine the effect of catalyst crystal structures and semiconductor electrical conductivity on catalytic activity. This was intended to support an electron transfer (as opposed to proton transfer) mechanism of AP decomposition. These delay time measurements complement other measurements relating to the onset of exotherms examined using DTA or DSC. The autoignition temperatures and delay times depend on the type of surrounding atmosphere and its pressure. It also depends on the purity of the AP before adding the catalysts and on the sample size.

Table 17: Autoignition temperature and activation energy of doped AP.

Author	Year	Additive	Minimum autoignition temperature		Activation energy		Atmosphere	Pressure
			K	°C	kJ/mol	kcal/mol		
Galwey and Jacobs [695]	1960	20% Carbon	533	260	167	40.0	Vacuum

Cd(ClO ₄) ₂	10:1	537	264	109.6	26.2		[513]
LiClO ₄	1:1	563	290			Very violent	[104]

The delay times for the autoignition of AP with the addition of 0.5 to 5% copper chromite at 563 to 573 K (290 to 300 °C) were 130 to 127 s [470].

The catalyst effectiveness of a group of metal oxides in lowering the autoignition temperature of AP decreased in the following order: CuCO₃, Cu₂O, CuO, Cu₂Cl₂, CuCl₂•2H₂O, with the ignition temperatures being 538, 548, 553, 558, and 560 K (265, 275, 280, 285, and 287 °C), respectively [511].

The critical ignition temperature T_{cr} depends on the AP sample weight and, in some cases, on the catalyst concentration. It does not, however, depend on the composition of the ambient atmosphere [700]. The measurement of the autoignition temperature of pure and catalyzed AP in the absence of any combustibles is done mostly for academic interests. Nonetheless, it can begin to gain practical value if the tests are repeated with added fuels (polymers, binders).

4.8 Effects of Diluents and Coatings on the Decomposition of Ammonium Perchlorate

DTA and DSC of undiluted AP show the phase change as an endotherm and exothermic decomposition before and, in particular, above the phase change. If there is an endothermic sublimation of AP it is overshadowed by the exotherms in pure AP. Attempts have been made to isolate the endothermic dissociation of AP into NH₃ and

HClO_4 by diluting it with 13% of polymethylmethacrylate (PMMA) [701]. A pulse calorimetric method was used for this reason and the samples were contained in a vacuum (initial pressure 0.05 mm Hg). At 573 K (300 °C) the mixture underwent an endothermic transformation, which has been related to the dissociation of AP. The magnitude of the endotherm (500 cal/g AP) was very similar to the theoretical heat of the dissociation of AP. PMMA does not react with AP at 573 K.

AP was coated with PS, cellulose acetate, Novolak (phenol/formaldehyde) resin, and poly(methylmethacrylate) using a solvent/non-solvent method. The effect of polymer coatings on AP decomposition was studied using TGA and DTA [702]. Polymer coatings resulted in retarding the decomposition of AP.

The LTD process of AP may play a critical role in the reaction violence during the cook-off of AP-based propellants. During AP LTD, the formation of linear voids has been observed to start at the AP particle surface and extend completely through the particle along a particular AP crystal plane. Voids are formed from the disassociation and formation of highly reactive species. These species degrade the propellant, resulting in a high level of grain porosity. This can result from slow/fast cookoff environments and those environments encountered after severe mechanical insults. It was hoped that coating and doping commercially available AP (200 microns) with inorganic salts or heterocyclic amines would extend the range of thermal stability.

4.9 Radiation Effects on Ammonium Perchlorate Decomposition

This chapter deals with the effects of radiation (UV, X-ray, γ -rays, or electron beams) on AP thermal stability and strand burning rates. The radiation may cause immediate decomposition or it may implant latent defects which will affect subsequent thermal decomposition and burning in rocket propellant. The current section deals only with AP itself. Similar experiments were conducted with formulated AP-based propellants under the influence of γ -radiation.

4.9.1 Decomposition of AP During Radiolysis

In the past, almost all radiation damage studies on explosives, propellants, or pyrotechnics were conducted by first irradiating samples and then, at a later time, performing some physical or chemical measurements to quantify the extent of radiation damage. There are a number of well-known reasons for performing radiation damage measurements **during** irradiation. One or more radiation-induced effects may decay rapidly and entirely disappear by the time measurements are made. Radiation may trigger or catalyze a reaction, which appears undesirable at a later time but might not be serious during the irradiation. Most importantly, radiation together with some functioning processes, such as propellant burning, may produce large synergistic effects.

The electrical conductivity of AP changed considerably after irradiation with γ -radiation from a ^{60}Co source, 4.5 MeV protons or X-rays. Applied doses ranged from 6.5×10^{-18} to 9.8×10^{-20} eV/g [158].

Decomposition measurements were completed in a constant volume chamber equipped with a capacitance manometer to determine total gas pressure [703]. This chamber was enclosed in a furnace that could be maintained at carefully controlled temperatures up to 973 K (700 °C). In addition, the sample chamber and furnace had optical-quality fused silica windows to facilitate optical absorption, luminescence, and taking other measurements during irradiation. Gas evolution studies were completed on AP single crystals and powder, both at room temperature and at 500 K (227 °C). Gas pressure versus time curve for commercial AP powder being exposed at approximately 100 R/s at room temperature increased in a smooth monotonic fashion. In marked contrast, the single crystal pressure curve showed abrupt burst-like spikes superimposed on a continuous background. The spikes appeared to occur at random times. They are most likely caused by the abrupt release of trapped gas and the subsequent partial readsorption taking place on the surface. Irradiating and heating at the same time caused a marked decrease in the induction period. Simultaneous heat and irradiation produced a large synergistic effect.

4.9.2 Effects of Pre-Radiation on AP Thermal Decomposition

AP-based propellants that are flying in outer space for long-duration missions may be subjected to cosmic radiation that alters their burning rate. Similar changes might occur in upper stage propellants during storage if in the proximity of missiles with nuclear warheads. In another scenario, upper stages during nuclear warfare (heaven forbid) might be subjected to intense radiation from nearby nuclear blasts before they arrive at their destination. Cast propellant grains are routinely inspected for voids using non-destructive examination methods such as X-rays or ultrasound. In all these cases, the potential changes in the burning rates of AP and AP-based propellants must be known. Even irradiation with less energetic UV light can bring about changes in AP crystals.

Irradiation via x-rays or γ -rays lowered the thermal stability of AP [648, 704]. The crystals exposed to radiation appeared to have specks of opaqueness throughout the solid. During decomposition, the opaque areas in the irradiated solid grew in size or were observed to form and grow throughout the entire crystal. When the dose of radiation was increased there was a sharp rise in the exotherm at 543 K (270 °C), which reached a maximum and then decreased. For samples receiving doses greater than 3.4×10^{-4} eV absorbed/molecule an early exotherm at 509 K (236 °C) occurred which increased with increasing dose. The four principal changes in the sequence of the decomposition of AP due to pre-irradiation were: **(1)** more vigorous reaction prior to and during crystalline phase transition, **(2)** strongly exothermic decomposition immediately following the phase transition, **(3)** more extensive reactions over the tempera-

ture range of 583 to 658 K (310 to 385 °C) and (4) a decrease in the extent of the final stage of decomposition at temperatures greater than 658 K (385 °C). The DTA decomposition pattern of irradiated AP was strikingly similar in detail to that of AP sublimate and of AP containing ClO_3^- ion impurities. The presence of ClO_3^- ions in irradiated AP was confirmed using wet analysis, however, they were not found to be present in the sublimate. $\text{ClO}_3^\bullet$ may also be present as free radicals [114].

The visual appearance of decomposing irradiated crystals as observed under a hot stage microscope under reflected light was significantly different from decomposing unirradiated samples [705]. The crystals were irradiated with a dose rate of 1.3×10^6 roentgen/h. On heating, there was a striking contrast between the behavior of the unirradiated and irradiated samples. Whereas in the former, the initial reaction occurred primarily at the surface while the latter irradiated sample underwent a reaction throughout the entire crystal. The apparent homogeneous clouding of the entire crystal indicates that nuclei for reactions were produced via radiation throughout the entire crystal. The irradiated crystals contained chlorate ions. Burning rates similar to irradiated AP could be obtained by doping clean AP with KClO_3 (which of course is a hazardous operation).

Free radicals and radiation damage in AP crystals can be detected using EPR spectroscopy [706]. The EPR spectrum corresponded to an unpaired electron spin strongly localized on an NH_3 molecule. Comparison of the EPR spectra at various temperatures indicated that the NH_3^+ ions were rotating freely at 373 K (100 °C) and the anisotropy observed at 298 K (25 °C) had disappeared. If there was any doubt after this experiment, it could be removed by repeating the test with isotope-labeled ND_4ClO_4 [707]. An additional transient peak was observed and attributed to $\text{ClO}_3^\bullet$. Analysis of the electron magnetic resonance of X-ray damaged AP crystals showed that the long-lived defects are NH_3^+ ions. Isotopic hyperfine splittings were found to be 54.6 MHz for nitrogen and 72.5 MHz for hydrogen. These radicals appeared to be planar and execute restricted rotation at room temperature.

The attribution of the extra peak to $\text{ClO}_3^\bullet$ has been confirmed by repeating the tests with isotope-labeled $^{15}\text{NH}_4\text{ClO}_4$ [708]. The electron spin resonance spectrum of NH_3^+ trapped in AP crystals (95% ^{15}N) was examined at 300, 77, and 4 K. The spectra were interpreted in terms of π -radical theory and demonstrated different stages in the freezing-out of the rotational motion of the ions.

The EPR spectrum indicated the presence of two paramagnetic species in irradiated AP: NH_3^+ and $\text{ClO}_3^\bullet$. The rates of formation and decay of NH_3^+ in both pure AP and AP doped with KMnO_4 , CaO , or MnO_2 were measured at 300–370 K [709]. The rate of NH_3^+ removal was

$$r = 10^{8.5} e^{-8300/RT} \text{ cm}^3 \text{ s}^{-1} \text{ mol}^{-1}$$

while the rate of $\text{ClO}_3^\bullet$ removal was

$$r = 10^{18} e^{-20000/RT} \text{ cm}^3 \text{ s}^{-1} \text{ mol}^{-1}.$$

The rate of $\text{ClO}_3^\bullet$ decay was thus much faster than the rate of NH_3^+ removal. The total concentration of paramagnetic species increased linearly with the dose D up to $D \approx 12$ megarad, after which it decreased rapidly, attaining a limiting value at $D = 18$. The energy of activation for the recombination of the NH_3^+ radicals in pure NH_4ClO_4 was $34.7 \pm 1.2 \text{ kJ/mol}$ ($8.3 \pm 0.3 \text{ kcal/mol}$). The recombination in the presence of CaO and KMnO_4 also is of the second order but with MnO_2 it is of the first order. The activation energy is $36.4 \pm 0.8 \text{ kJ/mol}$ ($8.7 \pm 0.2 \text{ kcal/mol}$).

The NH_3^+ ions take part in vibrational (translational) movement as well as rotation with a potential barrier of $2.3 \pm 0.21 \text{ kJ/mol}$ ($0.55 \pm 0.05 \text{ kcal/mol}$) [214]. The NH_3^+ ions vibrate preferentially anisotropically in the direction of the (100) face of the crystal, the same direction in which the decomposition progresses from the nuclei. This was established using a study of the temperature dependence of the hyperfine splitting in the EPR spectrum of the ion-radical NH_3^+ in single crystals of AP at $T = 77$ to 293 K (-196 to $+20^\circ \text{C}$).

Reagent grade AP was recrystallized twice from deionized water, dried, and then irradiated in stoppered test tubes with ^{60}Co at a dose rate of 0.36 Mrad/h [710]. No precautions were taken to exclude air from the specimens prior to radiolysis. The irradiated AP was dissolved in water and analyzed for chlorate, OClO , chlorite, hypochlorite, chlorine, chloride, and the total of nitrite plus nitrate. NO_3^- and NO_2^- were absent and ClO_2 and ClO_2^- concentrations were very small. The solution of irradiated AP oxidized ferrous ion in acidic media. All yields except that of ClO_3^- were essentially independent of the radiation dose over the range studied. The ClO_3^- yield, however, was observed to fall off and decrease at the higher doses. This probably indicates that ClO_3^- is undergoing radiolytic decomposition. AP radiolysis is quite different from that of metal perchlorates. The rate of AP decomposition is two to five times faster than that of alkali metal perchlorates (see [711, 712]).

The effects of $9.8 \times 10^6 \text{ rad}$ of radiation are a shortening of the induction period and an increase in the rate of three-dimensional growth during the acceleratory period of AP single-crystal decomposition [713]. At 500 K (227°C) the rate constant increased from $0.39 \times 10^{-2} \text{ min}^{-1}$ to $1.05 \times 10^{-2} \text{ min}^{-1}$ for the irradiated crystals. The induction period was shortened from 62 minutes to 5 minutes. The increase of the rate constant has been attributed to an increase in the number of decomposition nuclei. The crystals had turned opaque as the result of the radiation treatment.

The nature and kinetics of formation and recombination of paramagnetic species formed in ionic crystals of KClO_4 and NH_4ClO_4 under the effect of ionizing radiation (electrons, 1.6 MeV). These were investigated by measuring EPR spectra at 77 – 450 K [714]. Different mechanisms may be responsible for the accumulation and recombination of NH_3^+ and O_3^- free radicals in various temperature ranges.

For the decomposition of AP carried out under isothermal conditions, pre-irradiation caused a decrease in the induction period [715, 716]. The dependence of

an induction period on the absorbed dose could be described by the equation

$$I = C_1 - C_2 \log D$$

where I is the induction period, C_1 and C_2 are constants, and D is the absorbed dose.

Pre-irradiated AP was studied by itself and in a mixture with two different binders to determine the separate effects of radiation on oxidizer and binder (rather than compositely in a mixed propellant) [717]. AP crystals were subjected to 25, 60, and 129 megarad of γ -radiation from a ^{60}Co source and then incorporated into polybutadiene and polysulfide formulations. In all cases, severe mixing problems were encountered and cure times were increased. DTA of the irradiated samples revealed a displacement of the first exotherm from 713 K (440 °C) to 544–547 K (271–274 °C). Burning rate data indicated an increase in burning rate and pressure exponent for the 25 megarad irradiated samples. However, the samples with higher irradiation resulted in malfunctions. Heats of explosion for the 25 megarad formulation were lower than the non-irradiated formulations.

The DTA of irradiated AP was very similar to that of AP which had been doped with ammonium chlorate. Irradiation of AP using 200 keV X-rays resulted in a form of AP which decomposed considerably faster than an AP sample that had been adulterated by amending it with chlorate ions in amounts similar to that found in irradiated AP [180, 718]. The DTA of irradiated AP was very similar to that of AP doped with ammonium chlorate but not the same. Thermal decomposition of irradiated AP started before the polymorphic transition. It was suggested that the accelerated decomposition of AP is a result of cationic and anionic crystal lattice defects caused by irradiation. If irradiated AP is annealed for 200 hours at 373 K (100 °C), the effect of activation decreases but does not disappear entirely.

AP was modified using irradiation with 9.8 Mrad of ^{60}Co radiation and also via the use of thermal shock in liquid nitrogen [719]. Both treatments resulted in considerably enhanced rates of thermal decomposition. If sub-surface reactions determine the burning rate, one would expect that propellants containing AP modified in this way would burn faster. Surprisingly, this was not the case at 3.44 to 103 MPa (500 to 15000 psi) chamber pressure. It was concluded that sub-surface reactions do not control the burning rate at high pressures, however, they may well do so below 3.44 MPa (500 psi) (see [720] also).

Samples of AP were irradiated with γ -rays from a ^{60}Co source emitting approximately 1.1 Mrads/h for 30 to 1000 s [721]. After irradiation, the weight loss of AP samples was determined by weighing and then placing them in a constant temperature air oven maintained at 408 K (135 °C). Control samples that had not been irradiated were also placed in the constant-temperature bath. The samples were removed at various times and weighed. Essentially no gaseous products could be detected in the sample tubes during the first 280 hours while they were in the 408 K (135 °C) temperature bath. At the end of the 280 hours, a small peak on the mass spectrometer output was observed, corresponding to a trace of NO. The rate of weight loss increased with the

duration of radiation exposure. The rate change was most pronounced for the samples with 0 and 30 s, and did not change much beyond 1000 s. The induction time was found to be directly proportional to the log of the irradiation time for samples that had been irradiated for less than 1000 s.

Gamma radiolysis causes the formation of dislocations in crystals, which becomes visibly evident once the adsorbed dose goes beyond 10^5 rad and higher [722].

AP crystals were subjected to fast neutron irradiation or to fast neutron irradiation followed by gamma-ray irradiation [723]. Qualitatively, the radiation-induced changes were similar to those obtained in previous studies, with samples exposed to gamma rays only. The induction period was shortened and the rate constants, obtained from an Avrami-Erofeyev kinetic analysis, were different. The acceleratory period constant increased and the decay period constant decreased. When compared on an equal deposited energy basis, the fast neutron-induced changes were appreciably larger than the γ -ray induced changes. Some, or all, of the fast neutron-induced effects might be attributable to the introduction of localized regions of concentrated radiation damage caused by lattice atom recoils, which become nuclei for thermal decomposition sites when the crystals are later heated (see [724] also).

The thermoluminescence of single crystals of AP irradiated with X rays, UV light, or high energy electrons has been measured and found to be between 80 and 420 K [725]. With a heating rate of 5 K/min. prominent peaks occurred at 95, 113, 134, 246, and 320 K; an additional peak was found at 347 K after longer irradiation times. The absorption spectrum of UV-irradiated AP has also been measured and showed bands at 300, 360, and 610 nm. These peaks are most likely due to ClO_3^- , ClO^- , ClO_2 , and F centers as radiation products.

A dislocation model of the effect of pre-irradiation on subsequent thermal decomposition of AP was tested for the cases of the influence of X-ray radiation (copper cathode at 18 kV) and UV light (mercury quartz lamp) [726, 727]. An impervious mask shaded part of the crystal and a latent image was imprinted on the crystal. The effect of the development of the latent image by heating the irradiated crystal of AP was used as a test for the influence of pre-irradiation. It was found that the effect of pre-irradiation was exhibited rather clearly, even for small doses of irradiation with X-rays (10^2 – 10^3 rad), for which the corresponding density of dislocations is not changed. The same was true for irradiation with UV light.

The fact that the effect of pre-irradiation is exhibited for the small doses, which are three orders of magnitude below the threshold at which a noticeable increase in the number of dislocations is observed, was interpreted as an indication that the main factor responsible for the influence of pre-irradiation on the rate of thermal decomposition of AP is the formation of ClO_3^- ions (proton traps) in the lattice under the action of radiation.

When AP was mixed with 2 mass-% of either KMnO_4 , $\text{Ba}(\text{MnO}_4)_2$, or NH_4MnO_4 , an enhanced thermal decomposition of cubic AP was observed over the temperature range 528–573 K (255–300 °C) [728]. An even more pronounced effect was observed when AP was subjected to a radiation dose of 10 Mrad. The activation energy involved

over the acceleratory stage was found to be 46 kJ/mol for the irradiated AP, compared to the normal value of 85 kJ/mol. The value remained unaltered in the case of the first two additives, while in the presence of NH_4MnO_4 it decreased to 55 kJ/mol. Neutron bombardment did not change the decomposition characteristics of AP but some of the ^{38}Cl became radioactive due to neutron absorption and had highly damaged centers (see [729] also).

While normal AP decomposes in two stages (at 315 and 375 °C), 20% of weight loss occurred while at 160 °C when it had absorbed a γ -radiation dose of 1.0 MGy. Increased crystal size caused further changes in the TG/DTA curves. The weight loss approached 85% for particles that were 20 times larger. AP mixed with KCl/KBr in 1:1 ratio led to a formation of potassium perchlorate upon heating and the quantity increased progressively when the AP was pre-treated using irradiation. IR spectral investigations of decomposing irradiated AP provided information about intermediates formed during the decomposition of AP [382, 730].

The moisture sensitivity of the thermal decomposition of irradiated AP changed with the accumulated radiation dose [446]. Thermal decomposition and the evolution of decomposition products of γ -irradiated (dose: 0–3.6 MGy) AP at 373–593 K (100–220 °C) was followed by IR spectroscopy [731]. Increasing temperature and dose resulted in decreased peak intensities of NH_4^+ and ClO_4^- spectra. Loss of peak intensity was rapid up to 0.42 MGy dose, after which it slowed until it reached a 1.4 MGy dose. Radiolytic products $\cdot\text{ClO}_3$ and NH_3 were proposed to initiate the decomposition process using an electron transfer mechanism at an interstitial site in which ClO_4^- and NH_4^+ react to form $\cdot\text{ClO}_4$ and $\cdot\text{NH}_4$ radicals, which then decompose to form NH_3 and $\cdot\text{H}$ radicals (from $\cdot\text{NH}_4$ radical) and water and $\cdot\text{ClO}_3$ (from $\cdot\text{ClO}_4$ radical and $2\text{H}\cdot$ radicals).

A comparison of pre-irradiation AP, a pure sample, and a sample with added aluminum powder with protons, fast neutrons, and γ radiation showed that the most effective radiation is that accompanied by the formation of thermal peaks, as happens during irradiation with fast neutrons and with protons [732]. Irradiation with γ rays, which does not cause the formation of hot spots in perchlorate, was less efficient.

In continuation of these experiments, γ -radiation-induced decomposition of AP pelletized in a KCl/KBr matrix was followed by IR spectrophotometrically [733]. AP absorption peaks decreased in intensity as the γ -dose increased progressively. Irradiation of powdered AP produced ClO_3 ; its yield increased, attained a maximum, and decreased beyond a dose of 0.5 MGy. The result was similar but much slower in the case of γ -irradiated pellets of pure AP.

X-ray irradiation of AP leaves behind disturbed crystal lattice sites that hold $\cdot\text{ClO}_3$ free radicals. An ESR study of free radicals in X-irradiated AP single crystals was aimed at resolving the controversy that had arisen over the possible occurrence of low-temperature phase transitions in AP, which at room temperature has an orthorhombic structure (space group *Pnma*). ESR spectra were recorded as a function of the orientation of the magnetic field *H* in the three orthogonal crystallographic planes at 300, 77, and 4.2 K [114]. No changes in the spectra attributable to any phase

transition were observed. It was concluded that AP does not undergo any phase transitions below room temperature.

Radiolyzed AP oxidized aqueous iodide ions were placed in a solution when it was irradiated in combination with either aluminum, HTPB, copper chromite, or iron oxide. The influence was larger in the case of AP + HTPB and AP + copper chromite [734].

4.10 The Effects of Particle Size, Mechanical Agitation, and Nucleation Sites on Ammonium Perchlorate Thermal Decomposition

4.10.1 Effects of Particle Size on Slow AP Thermal Decomposition

Because particle size has such a pronounced effect on the burning rate of AP and AP-based propellants, it is important to know if particle size affects the thermal decomposition of AP as well. The effect may differ, depending on if the AP particles are surrounded by a polymeric binder or not. AP has varying combustion/decomposition modes depending on the particle size. Fine and coarse AP react via different mechanisms in solid propellants. Since coarse AP in particles larger than about 150 microns are used in the great majority for AP-oxidized solid propellants, the nature of coarse AP in propellant combustion has been studied extensively. Published investigations about AP thermal decomposition have provided insights into what is happening in coarse AP during the combustion of AP oxidized solid propellants. Spontaneous hole productions (porosity) in coarse AP particles during propellant combustion influenced by high thermal flux and in elevated pressure environments are greatly accelerated. However, this is similar to those observed in low-temperature AP thermal decomposition studies

The activation energy for the slow thermal decomposition of AP in the range from 413 to 598 K (240–325 °C) decreases with decreasing particle size (Table 19).

Table 19: Activation energy of AP decomposition as a function of particle size.

Particle size, μm	Activation energy ^a	
	kJ/mol	kcal/mol
<43	83.7	20.0
43–61	89.5	21.4
61–88	97.9	23.4
8–124	98.7	23.6

^abased on the simplified Avrami equation ($n = 4$)
Data source: [471].

The thermal decomposition of AP samples in the shape of 2-mm monocrystals, 265- μm granules, and 3- μm powders and pellets pressed at four and seven tons was studied

using DSC, TGA, and high-pressure DSC [735]. DSC of AP of different crystal sizes revealed that the occurrence and location of exotherms and endotherms in the thermograms depended on particle size. DSC data for a ball-milled 3- μm powder sample exhibited a sharp exothermic peak at 552 K (279 °C) followed by an endothermic event. A coarse granular sample (265 μm) showed a similar pattern of decomposition. However, the exothermic peak was less intense and occurred at a higher temperature (578 K = 305 °C). The subsequent endothermic event was similar to that observed for 3 μm powder. In contrast to the previous two samples, single crystals did not show obvious signs of an exothermic reaction but only an endothermic peak. Later stages of decomposition become endothermic under ambient pressure but can be turned exothermic at elevated pressures or in closed pans. TGA data also showed noticeable differences in the decomposition of samples with different particle sizes. Both the ball-milled 3- μm powder and the coarse granular samples revealed a two-step mass loss process. However, in 3 μm powder, the first step occurred at ~20% mass loss whereas in coarse AP it was at ~30%. For the large single crystal, the mass loss occurred in a single step and started at a higher temperature than in granular samples. DTA data on pressed AP pellets demonstrated a two-step process for two different pellet densities, just as for granular and ball-milled AP. However, these steps began and ended at higher temperatures. The pellet thermal behavior approached that of single crystals as the density of the pellets increased. A unique feature of the pellet experiments was the broadening of the phase transition peak at 513 K (240 °C), which is most likely associated with the large stress inside the pellets that slows down the transition to the larger volume cubic phase. The activation energy for the early stages of sublimation/decomposition for all samples started at ~120 kJ/mol, which was followed by a dramatic drop to ~60 kJ/mol at 20% mass loss. The activation energy for the later stages of sublimation/decomposition varied with sample type ranging from ~95 to 145 kJ/mol.

The decomposition of granular AP was studied under isothermal conditions in argon at atmospheric pressure by measuring the weight loss as a function of time [736]. For orthorhombic AP, the weight loss data were obtained for three size fractions at six different temperatures and analyzed using the Avrami-Erofeyev method, which provided the best fit for $n = 2$. The kinetic parameters for the induction period and decomposition were obtained and found to depend on particle size. For cubic AP, the weight loss of four size fractions was measured as a function of time at 519 K (246 °C). Comparable fits of weight loss data were obtained via the use of the monomolecular law and the contracting volume method. The results obtained for cubic AP indicate considerable changes in the decomposition behavior upon phase transition from orthorhombic to cubic AP.

Contrary to this, Jacobs and Russel-Jones found that AP particle size does not influence the decomposition rate at temperatures above the phase transition point (513 K = 240 °C) [131]. This was confirmed in later DTA tests using AP samples with 50 and 200 μm particle diameters [347]. An excellent book by Shteinberg [347] (p. 124–135) contains a detailed section on thermal decomposition and linear pyrolysis of AP under a variety of conditions. The activation energy under these conditions was 127–

133 kJ/mol for the entire range of the degree of conversion. A reaction scheme and equation for the HTD of AP were derived from these data, assuming that the HTD of AP occurs via two independent parallel reactions. In a first approximation, the fraction of AP decomposing due to the first (fast) step is constant. For the total reaction rate, the equation is

$$-\frac{dC}{dt} = k_1(T)C_1 + k_2(T)\sqrt{C_2}$$

which leads to

$$d\chi/dt = 2.2 \times 10^9 \exp(-32000/RT)(1 - \chi - Z + 0.02\sqrt{Z}),$$

where χ is the degree of conversion and Z is the root of the transcendental equation

$$\sqrt{Z} = 0.01 \ln(1 - \chi - Z) + 0.93.$$

In another study, it was found that 200 μm -sized AP particles could decompose to a 33% extent during AP LTD and 23% with 50 μm sized AP particles [389].

The thermal decomposition of two types of AP with different particle sizes was investigated using DTA and TGA-FTIR coupling [737]. It was proposed that the decomposition of AP crystals obeys the process of “topochemistry” and it was found that there are two steps in the decomposition of the coarse grain size. Based on the gaseous products identified in real-time using rapid scan FTIR, as reported results in existing literature, the different mechanisms of the two steps during AP decomposition process were interpreted and their dependence on particle size explained.

Kinetic measurements for the fine, medium, and coarse size fractions of AP revealed that the kinetic parameters changed with particle size [395]. The correlation between particle size and kinetics may be one of the reasons for the scatter in the kinetic data as reported in the existing literature. The proportion of AP converted to gaseous products became smaller as particle size diminished.

The activation energy of the thermal decomposition of UFAP is lower than that of regular particle size AP [738, 739].

In Figure 28, mass loss is plotted against time for isothermal experiments, which requires the heating of AP for two hours at 499 K (226 °C) with seven different sample sizes. An initial look at these results demonstrated that the decomposition rate of AP increased with a decrease in particle size. This set of experiments was duplicated to demonstrate reproducibility.

The following explanations were offered for the effect of particle size on the rate of AP decomposition: **(1)** The removal of reactants occurs through the surface and a decrease in crystal size improves decomposition reaction conditions by venting the products. **(2)** Grinding induces severe latent damage in the crystal structure and is assumed to be responsible for an abnormal reactivity of ground AP crystals. **(3)** In the absence of a binder, surface energy of small particles and/or humidity promotes the agglomeration of some particles to minimize entropy, so that the initial sizes of particles are not maintained.

Figure 28: The influence of crystal size (in μm) and grinding on the mass loss of commercial AP by heating to 599 K (226 °C) as a function of time. (Republished and modified from [401], with the permission of © 2009 John Wiley & Sons – Books; permission conveyed through Copyright Clearance Center).

A model of AP deflagration was developed, which takes into account the mechanism of its deflagration which is a balance of volume exothermic decomposition and surface processes (endothermic sublimation and redox reactions with heat release) [740]. Analytical expressions for the burning rate and combustion limits based on the heat balance on the burning surface were derived and compared to experimental results for AP with different particle sizes. It was shown that combustion failure occurs if the total thermal effect of the surface process is negative.

The morphology of AP thermal decomposition under purge gas and in a closed cell was studied experimentally using TGA measurements and SEM observations for four different particle sizes [449]. The AP was first dried at 388 K (115 °C) for four hours, then ground and sieved. AP samples with four different particle sizes were aged, i.e., subjected to a thermal stress test in a closed sample holder. The temperature program consisted of an isothermal hold for ten minutes at 298 K (25 °C), a ramp-up at 10 °C/min. to 498 K (225 °C), and isotherm hold at 498 K (225 °C) for three hours while the pressure in the closed bomb was recorded. To determine the fraction of unreacted product remaining after experiments in **closed** cells, the residues of pre-decomposed (“aged”) AP were collected and subjected to thermal decomposition via TGA **open** cell for 2 hours at 498 K (225 °C). The weight loss rate was recorded on a microbalance. Their micro-structure was studied by taking SEM images, illustrating the evolution of porosity in the granules. The influence of different parameters (particle size, temperature, and atmosphere) was then quantified using TGA. The type of containment is a key variable in the thermal decomposition of AP, along with the particle size, the surrounding atmosphere, and the temperature of the isothermal TGA. The mass loss

as a function of time for four different particle sizes demonstrate how the smaller particles decompose faster than the coarse particles (Figure 29 for closed cell conditions and Figure 30 for open cell conditions).

Figure 29: TGA mass loss of aged AP for four different particle sizes; Closed cell under air. (Reproduced and modified with permission from [449].)

$125\ \mu\text{m} \leq G1 \leq 160\ \mu\text{m}$, $160\ \mu\text{m} \leq G2 \leq 180\ \mu\text{m}$, $180\ \mu\text{m} \leq G3 \leq 250\ \mu\text{m}$, and $G4 \geq 250\ \mu\text{m}$.

Figure 30: TGA mass loss of aged AP for four different particle sizes; open cell with air purge. (Reproduced and modified with permission from [449].)

$125\ \mu\text{m} \leq G1 \leq 160\ \mu\text{m}$, $160\ \mu\text{m} \leq G2 \leq 180\ \mu\text{m}$, $180\ \mu\text{m} \leq G3 \leq 250\ \mu\text{m}$, and $G4 \geq 250\ \mu\text{m}$.

The results were similar if the aging tests were conducted in an open cell with an air purge instead of a closed cell. However, containment caused a decreased rate of thermal decomposition and the particles were less porous. For closed cell decomposition tests, the pressure rise rate was faster and the maximum pressure was higher for finely ground AP than for the coarse granules. Pores became visible sooner on the small particles than on the coarse particles.

The effects of various grain sizes (10–390 μm) on the rate of decomposition of AP at a heating rate of 40 $^{\circ}\text{C}/\text{min}$ and the decomposition thermal behavior and kinetic parameters (activation energy and pre-exponential factor) were investigated using simultaneous DSC/TGA in a dynamic nitrogen atmosphere [741]. In addition, the specific surface areas were measured using the BET method. The kinetic parameters were determined using a simplified approach based on the isoconversional method. The results revealed that the coarser the AP particle size was, the lower the determined decomposition kinetic parameters. The results were in acceptable agreement with findings in the existing literature.

Coarse AP displays some peculiarities that are not observed with smaller particle sizes. A good survey of the literature about the decomposition and safety properties of coarse AP by itself and incorporated in a binder system was published in 2014 [346]. When coarse AP crystals decompose, they produce porosity within the crystals which cannot be observed in small crystals. Porosity formation in coarse AP in both isolated crystals and during solid propellant combustion seems similar although it may appear at different rates due to pressure and temperature influences. Natural and acquired trace impurities are nuclei for porosity formation. In combustion environments, kinetic rates for coarse AP reactions can be altered by materials on crystal surfaces and occluded within the crystal bodies. Since reaction rates of orthorhombic AP crystals are much faster in combustion environments than those of cubic AP crystals, orthorhombic phase AP is a primary actor during combustions. Coarse AP oxidizer has observable chemical interactions that have not been observed for fine AP oxidizer during thermal decomposition and in combustion environments. Coarse AP oxidizer has widely different chemical kinetic reaction rates between low and high heat fluxes. Widely different reaction rates are also observed between low- and high-pressure confinements. In formulated solid propellants, coarse AP promotes dark zone combustion, a low burn rate pressure exponent, ease of burn rate adjustment, burn rate pressure exponent slope break, and slow cookoff violence.

4.10.2 Effects of Mechanical Agitation on Slow AP Thermal Decomposition

Changes in the density of dislocations and crystal defects in AP crystals as a result of mechanical treatment will affect the thermal stability of AP. It was shown that the mechanical treatment of AP under the action of shock waves causes substantial acceleration of low-temperature thermal decomposition [742]. This may be seen from the comparison of thermograms of mechanically treated AP and untreated AP. AP powder

that was exposed to a shock wave (of insufficient strength to detonate it) was subsequently tested using DTA and TGA. Although no chemical changes occurred in the AP, there was a considerable change in the number of lattice dislocations, resulting in an increasing number of pores. While for the mechanically treated AP the exotherm-peak corresponding to thermal decomposition on the DTA curve occurred before the phase transition at 240 °C, for untreated AP this peak did not occur until above the temperature region of the phase transition. The onset temperature of the LTD was lowered but the rate of the HTD was unchanged.

Prior compression or thermal treatment of orthorhombic AP resulted in a lengthening of the induction period and a decrease in the decomposition rate of the isothermal decomposition in the temperature range of 488–508 K (215–235 °C) [743]. The final extent of the decomposition also decreased from the usual 30% to ~20% for the materials subjected to prior treatment. Prior treatment caused a broadening in the XRD patterns and in the infrared spectra of AP subjected to prior compression and heating.

Two distinct regions of temperature dependence were observed for the rate constants of the decomposition of AP in its cubic modification in the temperature range 573–663 K (300–390 °C) [744]. The activation energies in the two regions were found to be 83.7 ± 8 kJ/mol (20 ± 2 kcal/mol) and 251 ± 8 kJ/mol (60 ± 2 kcal/mol). Prior mechanical and thermal treatment of the materials caused a marked increase in the thermal reactivity of AP in the range of 573–643 K (300–370 °C). DTA of pre-compressed AP showed pronounced changes in the exothermic decomposition of the material. Prior compression of AP also enhanced the sublimation of the material. The activation energies were not altered by the pre-treatment. It was assumed that the differences are due to crystal imperfections and the role of dislocations in the thermal decomposition of AP.

Intense vibration can cause sufficient cracks in AP crystals, which decreases their thermal stability. In one series of tests, two different size AP powders (2–5 µm and 160–300 µm) and single crystals (5 × 5 × 1.5 mm) were subjected to intense mechanical vibration for 30 s [745]. DTA of vibrated and non-vibrated samples showed that the phase transition and the two exothermic peak temperatures were shifted to lower temperatures.

Single crystals of AP that were strained by impressing the diamond tip of a hardness tester would subsequently react differently to shock damage than unstrained crystals. The type of defects this produced were analyzed using XPS (see Section 3.11.1).

It appears that high shear in the orifice of composite propellants extruders can alter the embedded oxidizer crystals. Microscopic analysis of AP crystals from an extruded HTPB composite propellant grain containing a star-shaped internal perforation configuration was conducted after an uncommon ignition phenomenon was discovered within 0.02 inches from the surface of the perforation. The morphological properties of the AP crystals mechanically removed from various areas of the extruded

propellant were compared with AP crystals not subjected to extrusion processes. The unusual morphology, due to a strained condition, was discovered using optical crystallographic techniques in AP crystals removed from the area suffering from unusual ignition phenomena [746].

Investigations of the origin of hot spots in deformed and shocked AP crystals also indicated that stressed and shocked AP decomposed at a different rate from the untreated material [192–194].

Deformation of RDX and AP crystals at low strain rates was studied via diamond pyramid (Vickers and Knoop) micro-indentation hardness testing [747, 748]. RDX is two to three times harder than AP and has relatively limited-slip system activity. While both crystals readily crack, cracking did not reduce hardness in RDX but did so in AP. Strain fields surrounding the hardness impressions in RDX were extremely localized, while in AP they extended well beyond the impressions. Shock experiments were conducted on large (5–9 mm) single crystals in a fluid-filled tank designed to permit high-speed photography and sample recovery. The reaction threshold was determined by varying the shock pressure entering the crystals. Shock-entry orientation and large hardness impressions were used to vary micro-structural responses. When a crystal with a large indentation was shocked near its reaction threshold, significant light appeared in the vicinity of the indentation following shock passage. High-speed photography showed **luminous crack propagation** and reaction in both materials and the same slip deformation in AP as from hardness testing. Orientation affected the micro-structural response and reaction threshold for AP, and hardness impressions sensitized chemical decomposition far from the impressions. Recovered AP crystals were much more plastically deformed than RDX crystals and were often still transparent in the region opposite shock entry. RDX reaction threshold was ~62 kbar versus 17 to 24 kbar for AP, depending on crystal orientation to the shock wave.

When studying the effect of ultrasound on the thermal decomposition of AP, it was found that significant changes in the thermal behavior of AP, as indicated by DTA and TGA, could be observed when AP crystals were subjected to powerful ultrasound while suspended in water [749]. The decomposition temperature of AP was lowered by nearly 25 °C. A similar thermal sensitization was observed when AP was subjected to sonication in the presence of transition metal oxides. Kinetic parameters were calculated for AP, modified AP, and catalyzed AP decomposition using non-isothermal kinetics. The activation energy for the decomposition of the sonicated AP samples was found to be lower than that of normal AP.

The thermal decomposition of AP catalyzed with different transition metal oxides. It was then subjected to ultrasound and studied using DTA and TGA. The onset temperature of AP decomposition was lowered by nearly 30–35 °C when AP was sonicated in an ultrasound bath in the presence of CuO [526]. The lowering of Ti was observed in other AP-metal oxide samples also, however, the sensitization was not so drastic.

Time-resolved Raman scattering measurements were performed on AP single crystals under stepwise shock loading [750]. For a particular set of temperature and

pressure conditions, the intensity of the Raman spectra in shocked AP decayed exponentially with time. This decay was attributed to a shock-induced chemical decomposition in AP crystals. A series of shock experiments, reaching peak stresses from 10 to 18 GPa demonstrated that higher stresses inhibit decomposition while higher temperatures promote it. No anisotropic orientation dependence was found when AP single crystals were shocked normal to the (210) and (001) crystallographic planes. The kinetic and spectroscopic results were consistent with a proton-transfer-reaction as the first decomposition step in shocked AP.

4.10.3 Effects of Nucleation on the Start of AP Thermal Decomposition

There are many AP decomposition studies that use single crystals. In these, the progression of decomposition sometimes documents itself by the initially clear crystal turning opaque as the crystal lattice changes and with the evolution of embedded bubbles. The decomposition zone often spreads and is clearly visible from crystal defects, which act as nuclei for the start of the reaction.

There are several publications reporting the study of nucleation in AP single crystals as the starting point for AP decomposition. Beyond the point of phase transition and lattice transformation from orthorhombic to cubic at 513 K (240 °C), the porosity of AP significantly increases. Sublimation products trapped in the voids and microcracks are in equilibrium with the solid phase.

Bircumshaw and Newman [348, 349] observed slow decomposition at 503 K (230 °C), proceeded by the formation of opaque spots (nuclei) on the crystal surface. These spots then grew in size and eventually coalesced to form a continuous opaque region. The boundary with the transparent region could be seen to progress inward toward the center of the crystal. Once the boundary reached the center of the crystal, decomposition ceased, leaving a porous pseudomorph, which was still pure AP but which had a density of only 70% of that of the starting product.

This porous material was further characterized using DSC, TGA, and DTG measurements [751, 752]. The onset of thermal decomposition temperature of porous residual AP is up to 50 °C lower than that of normal AP and the decomposition time span of porous residual AP is about 20% shorter than that of normal AP. Their thermograms are different in appearance but the same amount of heat is released. The first weight-loss stage of the decomposition of residual AP on the DTG curve occurs about 40 °C below that of normal AP. A catalytic effect was observed in the decomposition of pure normal AP when mixed with residual “infected” AP. The addition of a residue formed during LTD of AP can catalyze the subsequent thermal decomposition of clean AP. DSC results of normal AP in various particle sizes revealed that the surface area has no effect on the decomposition of normal AP. Therefore, this must be attributed to the internal crystal structure.

Nucleation sites are related to imperfections in the AP crystal, such as contaminants, inclusions, dislocations [753, 754], lattice defects, or stack faults. The movement and the multiplication of the nuclei in the zone of reaction and the number of

dislocations determine the AP decomposition rate [453]. At very high pressures, AP self-combustion exhibits anisotropic recession rates depending on whether surface regression is normal or transverse to the principal axis of its orthorhombic crystal structure. This behavior might be described as biaxial burning. The decomposition centers on AP single crystals which are anisotropic, cigar-shaped, and stretched along the principal diagonal of the rhombohedral face. The diameter of the reacting zones rarely exceeded $2\mu\text{m}$. The rate of expansion in the direction of rapid growth was about ten times faster than in the direction at right angles to the rapid growth. At 493 K (220 °C), the reacting zones can expand at a rate of $13\mu\text{m}/\text{min}$. Etching of fresh and partially decomposed, quenched crystals showed that fresh crystals contained a three-dimensional dislocation network, while etching of partially reacted crystals revealed the formation of new dislocations under the influence of stresses and strains near the reacting centers. The onset of AP LTD with coarse AP particles (~ 200 micron-size range) on a hot plate was observed with microscopes [755]. After variable induction period delays, dents appeared on the AP particle surfaces followed by the formation of elongated ellipsoidal holes extending from the dents. Gas evolution was noted as soon as holes in the AP particles appeared. Holes had a length-to-diameter ratio estimated to be about ten. Holes stopped growing after they had reached a certain size. The holes formed in parallel, only along a certain rhombohedral face or plane described as the [010] face. AP LTD started from crystal surfaces extending into AP crystals, with solid material being removed through conversion into volatile product gases. An estimate was made that the number of holes formed on $200\mu\text{m}$ AP particles were in the order of 10^6 per square centimeter. Below the phase transition point, the nuclei at the rhombic face of the crystal were cigar-shaped, while at the prismatic face they were round. The nuclei were near-spherical above the phase transition point.

The rate of growth of the nuclei is dependent on the amount of water present in the crystal to start with and the amount of water in the surrounding atmosphere [440] (see Section 4.5.1).

The effect of co-crystallized cation additives (incorporated into the lattice of AP) on the rate of formation of reaction nuclei were studied by [756], as was their maximum number per unit surface area and the rate of nucleus growth along the principal axis of the ellipse and what was perpendicular to it. It was found that the heterovalent ion additives (divalent cations) caused a decrease in the induction period, an increase in nuclei formation, and a maximal number of nuclei per unit surface area. At the same time, the additives did not affect the rate of nucleus growth in any directions.

If AP crystals are heated, the nucleation sites appear to be randomly distributed on the *c* face; on the *m* face some are randomly distributed but others lie along lines in specific crystallographic directions [757]. When crystals are strained before thermal decomposition, the nuclei are strongly aligned on both faces and oriented (with few exceptions) in the same crystallographic directions as similarly aligned pits formed by chemical etching. It can be concluded that the decomposition nuclei preferentially form where dislocations intersect the crystal surface. During heating at 443 to 483 K

(170 to 210 °C), the first-formed nuclei are widely distributed and appear to be predominantly located on the surface. These and subsequently formed nuclei cease growing once they reach a critical size. Additional nuclei continually appear between previously formed ones until a completely reacted layer is formed. Further decomposition occurs in two ways: The reaction progresses inward and becomes roughly parallel to the surface as successively deeper layers of nuclei are formed, or the reaction produces bands along (001) planes in the [010] and [510] directions. SEM examination revealed that these bands, as well as other parts of the reacted surface, consist of the porous residue of AP.

The shapes of nuclei are different at different faces of the crystal and depend on the temperature at which thermal decomposition is taking place. Below the phase transition point, the nuclei at the rhombic face of the crystal are cigar-shaped, while at the prismatic face they are round. Above the phase transition point, the nuclei are spherical. The growth of nuclei proceeds due to the formation of new seeds near the boundary of a nucleus. The cinematography of single crystals during decomposition helped to establish that the nuclei are moving along the diagonal of the rhomb at a velocity of 7–10 m/min. (for $T = 503 \text{ K} = 230^\circ\text{C}$). With even larger magnification achieved by using the SEM, it was discovered that the nuclei were initially not round as it was suggested earlier but that they have a clearly defined shape corresponding to the crystal chemical features of a given crystal face [403]. For example, on the rhombic face, the nuclei have the shape of a rhomb, while on the prismatic face they are rectangular. During decomposition, the nuclei reached the size of several microns and eventually stopped growing; their shape changes and they gradually become round.

One of the first steps of decomposition in an AP crystal may be the formation of nucleation sites around which the decomposition progresses and spreads like a cancer [758, 445]. The thermal decomposition of crystals of AP at low temperatures starts with the formation and growth of nuclei. To gain an understanding of the mechanism of the decomposition of AP, it is necessary to know which stages of the process are connected with nucleation and which lead to subsequent growth. It was proposed that nucleation occurs because of the course of the primary stage of the dissociation of salt and subsequent secondary reactions. It was also suggested that the growth of the nuclei is caused by the reaction of acidic decomposition products (HClO_4) with unreacted AP and due to the oxidation-reduction reactions of the active oxidizers being regenerated in the course of the process. The addition of strontium perchlorate or ammonium dichromate affected the nuclei growth rates.

AP doped with copper ions contains active sites around which decomposition is enhanced. Doping AP with copper ions does not change the density of dislocations as indicated by the number of etch pits. However, the number of dislocation sliding systems changes substantially [759].

Proton-acceptor additives are effective inhibitors of the nucleation process during the LTD of AP [760]. In contrast to this, the addition of ClO_3^- ion is a catalyst for the decomposition of AP. It increases the rate of nucleation and the maximum concen-

tration of nuclei and decreases the induction period of nucleation. It was found that impurities of ClO_3^- ions are typically present in even the purest commercial samples of AP. ClO_3^- ions may also form as the result of UV irradiation of AP.

The edge components of dislocations in ionic crystals carry an unbalanced electrical charge. Any ion chemistry at these locations may be affected by applying an external electrical field. A study of the effect of a constant electric field on AP single crystals found that a constant electric field with a field strength of 10 kV/cm affects the thermal decomposition in the crystal [761]. The anisotropy of reaction emanating from nuclei increases due to the prevailing growth of nuclei along the main diagonal of the rhombic face of the crystal. When the field was imposed along the direction [100], a decrease in the induction period and increase in the surface density of the initial reaction centers was observed. The number of dislocations may change as a result of mechanical strain arising in the crystal under the action of an electric field. It is unlikely that the burning rate of AP-based propellants can be modulated by applying an external electrostatic field, but on a microscopic scale this is possible.

Phenomenological surface texture changes occurring on the surface of decomposing AP crystals have been visualized using a replication micrographical technique [762]. Soon after attaining reaction temperature, (001) crystal faces develop residual saucer-like hemispherical depressions ascribed to bubble formation during water loss from superficial layers. Subsequently, small holes develop (which penetrate the crystal), as do regions containing parallel-oriented surface ridges.

Nucleation has also been discussed already in several other sections of the AP chapter in connection with the decomposition of AP (see [469] and [621] also).

Solid-state decomposition reactions generally start at specific sites. The first-formed product at these sites are referred to as “the nuclei”. Further reaction takes place at the interface between nuclei and unaltered reactant so that the first-formed nuclei grow in size. Visual observations of large nuclei revealed that these grow at a constant rate. However, in many solid-state decompositions, experimental evidence suggests a slower rate of growth for small nuclei, because the general kinetic equation based on nucleus formation and a constant rate of growth fails to adequately describe the early stages of the reaction before the rate accelerates [402]. In some reactions, structural changes induced by the reaction result in the multiplication (“branching”) of nuclei and a general equation (of which the Prout-Tompkins equation is a special case) can be derived. This general equation is shown to fit experimental data over a wider range than the original Prout-Tompkins equation.

4.11 Effects of Phase Changes on Ammonium Perchlorate Thermal Decomposition

AP undergoes a reversible polymorphic transition at 513 K (240 °C). This temperature is close to its melting point and its point of incipient thermal decomposition. Below 513 K, AP exists in the form of orthorhombic crystals. Above 513 K AP exists in the form

of cubic crystals. The phase transition orthorhombic $\rightarrow$ cubic is endothermic but it is often accompanied by incipient thermal decomposition. Thermal decomposition of AP proceeds differently, depending on if one starts with the orthorhombic or cubic modification. Also, the effect of additives on the dissociation of AP is different, depending on which modification exists at the moment when the additive steps into action [110].

A gravimetric method was used to study the kinetics of crystallographic phase transitions in AP with a particle size of 0.2–0.7 mm upon heating (443–573 K = 170–300 °C) in a vacuum. The anomalous temperature dependence of the reaction rate is caused by a phase transition from orthorhombic to cubic NH_4ClO_4 and by the self-crushing of part of the sample in the later stages of the reaction. The rate of thermal decomposition sharply decreased at the moment of phase transition because the rearrangement of the lattice from a rhombic into a cubic structure leaves no space for decomposition products to accumulate in the crystals [763] (see [764] also).

4.12 Computational Chemistry in Support of the Study of Ammonium Perchlorate Thermal Decomposition

With the advances of computational chemistry, several theoretical studies have looked at the decomposition of AP either as a purely theoretical study or as a way to complement and support experimental studies. Similar computational efforts have been made with other self-decomposing oxidizers like ANI ADN.

Catalyzed and uncatalyzed thermal decomposition of AP was investigated at different temperatures in the range 493–588 K (220–315 °C) using different size particles and the data fitted to a math model [765]. The data were fitted using an integrated form of the relation

$$\frac{dy}{dt} = \frac{ay - by^2}{1 + cy}$$

where y denotes the fraction decomposed at time t and a , b , and c are constants. At lower temperatures $dy \ll 1$, while at higher temperatures $dy > 1$. The constants a , b , and d depend strongly on temperature. The energy of activation of the processes associated with a and b was 188 ± 4 kJ/mol (45 ± 1 kcal/mol), while that for d was 176 ± 4 kJ/mol (42 ± 1 kcal/mol).

There have been numerous investigations into the mechanisms of AP thermal decomposition. Products that have been observed under various conditions, in what are evidently rather complex processes, include HCl, H_2O , N_2 , O_2 , NO, NO_2 , N_2O , Cl_2 , ClO, and HClO_3 . Attempts have been made to theoretically predict thermodynamic data relevant to the various steps that may be involved in AP thermal decomposition. The structures, energy minima, and enthalpies at both 298 and 800 K for 37 atoms, molecules, and ions that are possible intermediates or products were calculated [766].

These data permit the calculation of ΔH_{298} and ΔH_{800} for hundreds of reactions that may be involved. Thirty-nine of these are listed in [766] and several possible decomposition pathways are outlined. ΔH_{298} and ΔH_{800} were found to differ by less than 1.0 kcal/mol. The activation energy of sublimation is considerably less than its overall enthalpy change. Figure 31 depicts some possible pathways for the thermal decomposition of AP. It is likely that several of these (as well as others) proceed simultaneously and include other steps in addition to those shown.

Figure 31: Some of the possible steps in the decomposition of AP. (Republished from [766], with permission of © 1998 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center, Inc.)

Note: This scheme shows reaction paths for which the heat at reaction points 298 K have been computed. The numbers in parentheses are the numbers of the reactions in a table (not shown) that gives kinetic parameters.

A theoretical study of a series of ClO_x reactions relevant to the combustion initiation of AP included the decomposition of ClO_x ($x=2-4$) and HOClO_y ($y=2-3$), the bimolecular reactions of $\text{HO} + \text{X}$ ($\text{X} = \text{ClO}, \text{OCIO}, \text{HOClO}_3$), $\text{ClO} + \text{Y}$ ($\text{Y} = \text{O}, \text{ClO}, \text{OCIO}$),

H + HOClO₃, and some of their reverse processes [767]. The geometries of the reactants, intermediates, transition states, and products involved in these reactions were optimized by a computational method and final energies were refined. This allowed rate constants for major product channels to be predicted and compared with the available experimental data. Detailed mechanisms for these reactions were then discussed on the basis of predicted potential energy surfaces. The rate constant calculations were carried out using conventional transition state theory (TST), or Rice-Ramsperger-Kassel-Marcus (RRKM) theory. This was used for reactions with well-defined transition states and variational TST. RRKM theory was used for those channels which occur without barriers. The results showed that predicted energies and rate constants were quite satisfactory and in good agreement with available experimental data.

A computational study of AP decomposition and a comparison of the gas-phase and condensed-phase reactions led to the conclusion that strong solvent effects may exist in the AP decomposition reaction [400]. The mechanism considered included the following initiation processes in the solid, liquid, and gas phases:

The results showed that, in the gas phase, the main decomposition channel of AP is the proton transfer from the ammonium cation to the perchlorate anion. This forms ammonia (NH₃) and perchloric acid (HClO₄):

with 59.4 kJ/mol (14.2 kcal/mol) enthalpy change. In solution, the enthalpy change for this channel is 123.4 kJ/mol (29.5 kcal/mol), which is close to the sublimation activation energy (~125.5 kJ/mol = ~30 kcal/mol) in crystalline AP. The other possible channel

has higher enthalpy changes, of 235 kJ/mol (56.3 kcal/mol) and 322 kJ/mol (77.1 kcal/mol) in the gas phase and in solution, respectively, and is less probable. This data indicates that strong solvent effects may exist in the AP decomposition reaction. As shown in Figure 32, the activation energy for the transfer of a proton from the ammonium cation to the perchlorate anion in the gas phase at transient state TS1 is only 2.1 kJ/mol (0.5 kcal/mol). This is considerably lower than the expected value (~125.5 kJ/mol = ~30 kcal/mol) for the proton transfer process in the crystal. This is expected since the surrounding ionic coulombic attractions and hydrogen bonding in crystals are not present in the gas phase. The existence of ion pairs in the gas

phase is not favored energetically (with $467 \text{ kJ/mol} = 111.7 \text{ kcal/mol}$ endothermicity). The production of perchloric acid and ammonia is preferred with only 59.4 kJ/mol (14.2 kcal/mol) endothermicity from the metastable LM1 complex. The second channel, based on a PCM, proceeds by way of the production of ClO_3 and an $\text{H}_3\text{N-HO}$ complex. This has a heat of reaction of 235 kJ/mol (56.3 kcal/mol).

In an effort to explain how water affects proton transfer on the surface and on solid AP, gas-phase reactions were simulated by computational chemistry methods at various levels of complexity. This involved the use of a generalized gradient approximation with a plane-wave DFT [443, 444, 768] (see Section 4.5.1). Dissociation mechanism and the role water molecule(s) play(s) in the surface decomposition process were compared to those in the gas phase and in solution.

With the increasing capabilities of kinetic modeling software, solid/vapor reactions can be modeled, as can homogeneous gas-phase reactions. A simulation of the combustion of AP with and without contact with a combustible HTPB binder was carried out using Chemkin software. This took place in two stages: during the burning behavior of pure AP and one of AP in contact with HTPB binder [769]. In both cases, the chamber pressure was varied in order to verify its influence on the burning rate. The results were plotted using two different methods: at first as a time-resolved graph and later as a spatially resolved graph. The composition was measured as a function of the distance from the burning surface. The flame structure, composition profile, and

temperature profile could be described by the mol fractions of the burning products and the temperature evolution from the surface of the material to the peak temperature in the flame front.

5 Combustion (= Deflagration) of Ammonium Perchlorate

The word *combustion* is commonly used for reactions of fuels with oxidizers as well as the flame-producing decomposition of energetic materials, typically monopropellants. A more accurate term would be *deflagration* because it describes the decomposition without the aid of an external oxidizer or fuel. We use the two terms here interchangeably. The deflagration of AP by itself and the combustion of AP-based propellants have been extensively investigated for the past sixty years. Once, an entire session of the 11th Symposium (International) on Combustion in 1967 was devoted to AP. The objective of most of the studies was to develop propellants with higher burning rates (in particular for air- and missile-defense applications) and to maintain a reproducible, zero-defect production of the standard AP-based propellants used in Minuteman and M-X/Peacekeeper intercontinental ballistic missiles (ICBM's) and in large strap-on boosters.

5.1 Ignition of Ammonium Perchlorate (No Binders)

This chapter deals with the combustion of AP itself in the absence of fuels or binders. Before AP can burn, it must be ignited. Many studies concentrate just on the initial phase of AP ignition and combustion. This is closely related to measuring the induction periods for the autoignition of AP, when it is heated to a preset temperature and held at that temperature until ignition occurs (see Section 4.4). Numerous studies deal with the ignition of formulated propellants containing AP as the oxidizer.

The ignition of AP, with and without catalysts and a simulated binder (polyethylene), was studied in an arc furnace [601, 602]. A thermal runaway in the condensed phase can account for the ignition phenomena observed. Ignition cannot be interpreted solely as the time required to establish steady-state conditions but is a complex sequence of events. The outcome is different if the exothermic reaction occurs in the condensed phase or in the gas phase. In the case of AP, it was concluded that a condensed-phase reaction is a necessary prerequisite for ignition.

In trying to clarify if AP ignition occurs in the condensed phase or in the gas phase, the AP sublimation-dissociation-ignition multi-step process was separated by simulating only the vapor phase ignition. This was done by impinging jets of perchloric acid and ammonia (and other combustible solids and vapors) with and without the presence of catalysts [770, 771]. Perchloric acid/ammonia/catalyst mixtures ignited faster than perchloric acid/solid fuel mixtures. It was suggested that, for AP subli-

mation products, ignition occurs as a result of heterogeneous reactions between ammonia and perchloric acid vapor on the surface of catalyst particles. Perchloric acid/ammonia ignition was catalyzed using copper(II) chromate or iron(III) oxide, the same substances that also catalyze AP decomposition and ignition.

The ignition and combustion behavior of both pure AP and laminated AP/fuel/AP sandwiches of millimeter slab thickness were studied using a technique that utilized a CO₂ laser beam to supply radiant energy to the surface of an igniting and burning propellant [772, 773]. The burning rate of pure AP as a function of incident laser power density, the ignition delay duration of pure AP as a function of pressure and laser power density, the gas composition and flame temperature for the laser-induced AP flame, the flame structure and flow field from linearized propellant sandwiches of pure AP and PMMA fuel-binder, and the compositional and thermal structure of the AP-PMMA laser-induced flame were measured. The sandwich burning data revealed the gas-phase structure of the fuel-oxidizer interdiffusion flame.

A simplified theory for the ignition of AP was proposed, which was derived from a unified theory that also explained the low-pressure deflagration limit (LPDL) as well as the steady-state deflagration [774, 775]. The theory provides an approximate method for calculating ignition delay and the minimum external heat flux required for a successful ignition (as functions of pressure and initial solid temperature). The ignition calculations revealed that there exists a pressure limit due to the weakness of the igniter strength, in addition to the LPDL, which is an inherent property of the solid independent of the igniter strength. The theory can be extended to other solid monopropellants for which exothermic reactions occur only in the gas phase. The ignition temperature of AP is lowered by the presence of fuel-rich compounds [776]. Chapter 11 of a two-volume set of books on *Energetic Materials* contains a section on the reliable prediction of kinetics and mechanisms for elementary processes in the chapter “Key Combustion Initiation Reactions of AP” [777].

5.2 Strand Burning of Ammonium Perchlorate (No Binders)

There is some overlap between this section and the previous sections which looked at the thermal decomposition of AP with traditional chemical methods without measuring the linear regression rates. The following sections extend those studies with measurements of actual burning rates of AP by itself (without the addition of combustible binders). The rates of thermal decomposition and the burning rates are both affected by various additives (contaminants, catalysts, inhibitors) and operating conditions (initial temperature, pressure, venting, or confined) in a similar way. With adequate precautions, cylinders of compacted AP without a binder can be burned in a Crawford bomb similar to AP-containing solid propellants. In trying to increase the burning rates of propellants, the effect of burning rate additives on the burning rate

of AP-based propellants was quite often first studied with AP alone, thus avoiding any interference from the type of binder used. The next step then would be to try the same burning rate additive in an actual propellant formulation with a fuel present.

The ability of AP to maintain a solid monopropellant-like decomposition reaction (= deflagration) is unique among the solid propellant oxidizers and is shared with only a few other oxidizers, all ammonium, hydrazinium, or hydroxylammonium salts, although stable combustion can only be maintained at very high pressures. For this reason, a very large number of experiments have been performed to examine the strand burning of AP without the addition of fuels. The burning of individual crystals of AP (surrounded by a binder) plays a vital role in establishing the burning characteristics of composite AP-based propellants. Sometimes during such experiments, combustion may cease after initial successful ignition. This indicates that the failure is a propagation problem and not an ignition problem. Combustion of AP in the absence of combustibles is easily quenched by external interference.

Combustion and decomposition processes for AP can take place at temperatures above 513 K (240 °C) directly from the orthorhombic phase. This is because the speed of phase transition to the cubic phase is so slow that advancing burn fronts may move faster than the phase change process. AP is less thermally stable in the orthorhombic phase than in the cubic phase, as shown by differences in mass decomposition rates in the orthorhombic phase compared to the cubic phase until temperatures reach 573 K (~300 °C) or more.

5.2.1 Experimental Methods for the Study of Strand Burning Rates of AP

The rate of burning of AP pellets can be studied by embedding micro-thermocouples or break wires in the pellet or by relying on visual observations (high-speed camera recording) in a windowed bomb. The pressure measurement alone in a constant-volume bomb is not a very accurate indication of the linear burning rate. The surface of quenched AP samples can be examined under the microscope and will reveal details about the structure of the melt layer and crack formation in the underlying solid [778]. High-speed movies of the burning surface have also been recorded [779].

The electrical conductivity of the condensed phase of burning AP was measured at pressures between 26 kPa (200 mm Hg) and 10.1 MPa (100 atm) [780]. Electrical conductivity at 293–573 K (20–300 °C) is caused by the more mobile NH_4^+ ions, and to a lesser extent, by ClO_4^- ions. The gas in close proximity to the burning surface is in a plasma state.

Attempts have been made to measure the A.C. electrical conductivity of the combustion zone of a deflagrating AP pellet in a direction perpendicular to the travel of the flame front [781]. The ohmic resistance was measured as a function of frequency at 1–20 MHz. It was attempted to Differentiations between the conductivity of the melt layer and the ionized flame front were sought.

5.2.1.1 The Linear Strand Burning Rates of AP

The linear strand burning rates depend on the homogeneity of the sample. The most homogeneous sample structure could be achieved with slabs sliced from selected faces of large single crystals. However, these are more difficult to obtain than pressed pellets. Even pressed pellets are not identical; it depends on the particle sizes of the powders from which they were made and on the amount of compaction and residual porosity. The following sections discuss linear strand burning rates of pressed pellets and single crystals of AP under a variety of conditions that affect the burning rate.

In addition to measuring linear strand burning rates and plotting them against pressure, other studies have measured the weight (mass) loss rate and the electrical conductivity and used this as an indication of the progression of the flame front.

Literature on more general (with no emphasis on a specific variable like pressure or catalysts) studies of AP deflagration and linear burning rates are summarized here in chronological order. Some of the investigators may have added burning rate catalysts, while others may not have done so.

Crystalline AP sublimates to ammonia and perchloric acid vapors via an endothermic process. Heat is generated in a gas-phase oxidation-reduction process, which is perhaps 10^{-5} cm (30 mean free paths) above the surface at 10.1 MPa (100 atm). The final temperature is 1203 K (about 930 °C) but the surface temperature is 100–200 K cooler. Heat is conducted back through this thin layer to supply the energy for preheating and vaporizing the crystal. The propagation rate is governed primarily by the rate of heat generation in the gas phase and the thermal conductivity of the gaseous layer just above the surface. Catalysts accelerate the burning rate by projecting from the surface into the thin gaseous reaction zone then producing local acceleration of the reaction rate. The low-pressure flammability limit is caused by radiative heat loss to the surroundings.

The rates of pyrolysis of AP were measured by pressing a pellet of AP against a heated porous plate [782]. The pyrolysis products could escape through the porous plate where they would no longer interfere with the pyrolysis process. Ammonium chloride, which was non-reactive, was tested in the same apparatus along with AP for comparison. Data compared well with similar data obtained earlier with a compact hot plate instead of a porous plate.

An experimental study of the process of linear pyrolysis of AP at temperatures below 773–823 K (500–550 °C) observed that a stationary flameless decomposition took place [365]. The kinetic constants determined from these experiments corresponded with the data obtained under isothermal conditions. At temperatures above 773–823 K (500–550 °C), NH_4ClO_4 gasifies rapidly and was accompanied by combustion of the products of pyrolysis (see [783] also).

The exothermic decomposition reaction in the condensed phase, followed by sublimation, has been considered as the basic mechanism of AP burning. The kinetic retardation or acceleration of the burning process has been connected with a change of equilibrium concentration of HClO_4 . This was limiting the decomposition under the

influence of sublimated components of different solubility (NH_3 and HClO_4) as well as decomposition products (H_2O and HCl), which shifted the equilibrium state of the reaction

The formulas obtained explain the main characteristic features of the dependence of the burning rate of NH_4ClO_4 on pressure; namely, the initial growth of burning rate with pressure, the plateau or the rate drop, and the subsequent growth at high pressures [784] (see [785] also).

Sample preparation variability influences the rate of AP deflagration and may overshadow the effects of pressure, sample temperature, and acceleration environments on the burning rate [786]. The sample preparation parameters investigated included pellet compaction time and pressure, the particle sizes of the AP powder from which samples were pressed, and the type of AP (ultra-pure, propellant grade, and propellant grade with conditioners) from which the pellets were made.

The strand burning rate of AP by itself may vary from batch to batch depending on its source [787].

5.2.2 Effects of Pressure on the Strand Burning Rates of AP

The dependence of the linear strand burning rate of AP on pressure is the same as that of AP-based solid propellants. This has been thoroughly investigated, sometimes with side-by-side AP-based propellants which are then compared to the oxidizer. The burning rate obeys the Roberts-de Saint Law. Therefore, one needs to determine the pre-exponential factor and the burning rate coefficient to derive combustion theories of AP-based composite propellants. The main question is how the burning rate of AP-based propellants is affected by the condition of the oxidizer in the absence of binders. Since up to 80% of most propellants consist of AP, it has a major impact on the burning rates of formulated propellants.

When conducting burning rate studies, one must differentiate between self-sustained (adiabatic, free pyrolysis) and aided (non-adiabatic, forced pyrolysis) combustion [788]. The combustion of AP in a composite propellant will be a forced pyrolysis since an appreciable fraction of the heat released during the fuel/oxidizer combustion process is fed back to the surface. During experiments in the temperature range of 590 to 1540 K and at pressures between 2.6 kPa to 2.62 MPa (0.026 to 26 atm), it was noted that above 910 K the results were well-represented by an empirical relation which expresses the pressure dependency of the regression rate. Below 2.12 MPa (21 atm) and at a given pressure, the regression rate increased with increasing temperature, whereas it decreased above 2.12 MPa (21 atm). The burning rate or free pyrolysis rate is proportional to the 0.5th power of the pressure at low pressures (1 to 5 atm) and to the 0.9th power at higher pressures. The pressure exponent of the AP regression rate under free pyrolysis conditions (0.505 to 10.1 MPa = 5 to 100 atm) can be compared to the max-

imum values found for the pressure exponents of solid propellants. At low temperatures, the regression rate was not sensitive to pressure.

The rate of deflagration of pressed pellets of AP was measured at different ambient pressures and temperatures, with initial particle sizes ranging from a few microns to several hundred μm in diameter [789]. The density of the pressed pellets was 1.908 g/cm^3 for the as-received material; 1.894 g/cm^3 for the 74-to-105 μm fraction; and 1.896 g/cm^3 for the minus 53 μm fraction. The single-crystal value should be 1.95 g/cm^3 . These results indicated that the material was not perfectly compacted although the molding pressure of the pellets was 100000 psi. No luminosity of the products of deflagration could be seen except for the occasional flashes believed to be due to impurities. Condensation of the combustion products was evident as the high-pressure, moisture-laden gases mixed with the cold ambient nitrogen to form an acid fog. At an ambient temperature of 294 K (21°C), lower and upper deflagration limits were about 4.54 MPa (45 atm) and about 30.3 MPa (300 atm), respectively, for AP pellets pressed from as-received powder. When such pellets were preheated to 343 K (70°C) instead of to 294 K (21°C) before ignition, deflagration rates increased at all pressures. Further, deflagration could be maintained down to nearly 2.02 MPa (20 atm). The pressure above which the deflagration rate began to decrease was raised from 15.15 to 20.2 MPa (150 atm to 200 atm). At higher pressures, however, a novel phenomenon was encountered. The existence of an upper-pressure limit, which is only slightly dependent on particle size but may be raised by preheating, occurred. When the pellets were precooled to 255 K (−18°C), ignition could not be obtained at any pressure.

The deflagration behavior of pure and doped AP was studied over the pressure range 2.064–41.28 MPa (300–6000 psia) using cinephotomicrography of burning samples and SEM of quenched samples [779, 790]. Materials tested were pure AP in single-crystal and pressed-pellet forms and single crystals with controlled isomorphous substitutions of K^+ , MnO_4^- , and $\text{Cr}_2\text{O}_7^{2-}$ ions. The results showed that previous speculations regarding the combustion of AP were based on erroneous assumptions. As such, more realistic views based on these observations were proposed. Some questions regarding the relevance of low temperature, low heating rate, and low-pressure decomposition data to actual combustion in propellants continue to be discussed nowadays.

5.2.3 The Effect of Temperature on Strand Burning Rates of AP

The dependence of the linear strand burning rate of AP on temperature is the same as that of AP-based solid propellants and has been thoroughly investigated [791]. Besides temperature and pressure, there are many other variables that can affect the burning rate of AP and those will be discussed in subsequent sections, including pellet density, particle size, and effect of additives. These variables need to be kept constant if one wants to obtain accurate data on the pressure or temperature dependency of the AP burning rate. Similar temperature dependencies were measured with AP that was doped with various additives. It was later recognized that the temperature sensitivity of the deflagration rate of pure AP is less than previously reported [792].

In extending conventional burning rate and pressure exponent measurements, additional data was used to determine the temperature sensitivity coefficient σ_p of the burning rate of AP and four other oxidizers [793]. The simplest means of determining a value of σ_p is to measure the burning rate of a particular material as a function of initial temperature, take the natural logarithm of the burning rate values, and determine the burning rate temperature sensitivity as the slope of the line through a plot of the natural logarithm of the burning rate versus the initial temperature. The main requirement is to obtain a consistent and reliable set of burning rate data at various initial temperatures and pressures. In the case of AP, the temperature sensitivity goes through a minimum over a wide pressure range (Figure 33).

5.3 Linear Strand Burning Rates of Ammonium Perchlorate Pressed Pellets

Most AP deflagration and burning studies were done with pressed pellets. These have inhomogeneities and varying degrees of porosity which may affect the burn rate. It is very difficult to press AP pellets with reproducible porosity and burning behavior.

It is surprising how much scatter there is if the burning rate data from eight different investigators are plotted together on the same graph, as has been done in Figure 34. While the data agree quite well with each other in the low-pressure regime up to 13.76 MPa (136 atm = 2000 psia), there is a lot of scatter at pressures above 13.76 MPa (136 atm = 2000 psia). In particular, the U-shaped burning rate minimum at 20.6 MPa (204 atm = 3000 psia) has not been observed by all experimenters, the reason for which is hard to explain.

5.3.1 The Effect of Bulk Density on Linear Strand Burning Rates of AP Pressed Pellets

The burning rate of pressed AP pellets is highly dependent on the bulk density of the pellets. It is difficult to press AP powder reproducibly into pellets with uniform burning characteristics. AP was pressed into 10 mm diameter pellets and burned in a strand burner under nitrogen at varying pellet bulk densities (0.65 to 1 g/cm^3), particle sizes (15 to $140\text{ }\mu\text{m}$), different pellet confinements, and two different chamber pressures (60 and 100 atm) [266]. The main objective of the study was to measure the effect of bulk density on the burning rate of pure AP pellets. Urotropine or bitumen was added only for comparison.

The burning rate of AP was measured as a function of the pressure (up to $14.1\text{ MPa} = 140\text{ atm}$), the initial pellet temperature ($293\text{--}393\text{ K} = 20\text{--}120\text{ }^\circ\text{C}$), the size of the particles ($50\text{--}400\text{ }\mu\text{m}$), and the density of the pellet ($1.5\text{--}1.9\text{ g/cm}^3$) [795, 796]. The burning rate increased with an increase in pressure and tends to reach a point of saturation when it reaches a range of $9.09\text{--}11.11\text{ MPa}$ ($90\text{--}110\text{ atm}$). This dependence cannot be described by the known empirical formula $r_b = Ap^n$ since A and n depend strongly on the pressure. The data obtained was not in agreement with the theory of the combustion of volatile substances developed by Zeldovich, and even contradicted it in some cases. The addition of NH_4Cl lowered the temperature of the reaction layer

of the condensed phase and increased the minimum temperature of combustion. If the process takes place in the condensed phase, the addition of NH_4Cl should decrease the rate of combustion. However, it increased it in the gas phase instead.

It is interesting to compare the effect of packing density on the linear strand burning rates of AP and, at the same time, compare it to the burning rates of other nitrogen based (hydrazinium and hydroxylammonium) perchlorates, as shown in Figure 35.

Figure 35: Linear strand burning rates of AP and other perchlorates. (Reproduced and modified from [7].)

In powder form at 1.11 g/cm^3 (top trace, solid line), AP burns much faster and erratically extends to lower pressures (dashed line). However, compressed AP pellets at 1.90 g/cm^3 (the range bracketed by two parallel dashed lines) burns much slower and does not burn at lower pressures. Hydrazinium perchlorates are in between the two AP extremes and burn at lower pressures. The data set for hydroxylammonium perchlorate powder was only for a narrow pressure range but seems to be linear.

5.3.2 Effects of Particle Size on Linear Strand Burning Rates of AP Pressed Pellets

Improved reproducibility of burning rate data was achieved by conducting all tests at 333 K (60 °C) [795]. Up to 7.57 MPa (75 atm), the burning rate agreed well with a linear $r=f(p)$ relationship but the pressure exponents ranged from 0.2 to 1.2. The burning rate increased with an increase in the size of the particles (in the range from 250 to 315 μm), leveling off in the range of around 315–400 μm and converging at high pressures for all sizes. The pressure characterizing the lower pressure limit of stable combustion decreased with increasing particles size. The linear burning rate increased with an increase in density. The temperature coefficient of the burning rate

$$\sigma_p = \left(\frac{\partial \ln r}{\partial T} \right)_p = \frac{1}{r} \left(\frac{\partial r}{\partial T} \right)_p$$

decreased with an increase in pressure and size of the particles and showed a tendency to level off. The limiting pressure of combustion decreased with an increase in temperature. The smaller the size of the particles in the pellet the more strongly it decreased. It was suggested that all these results could be explained on the basis of an exothermic reaction in the condensed phase. However, the fact that the burning rate increases with pressure is a strong argument for exothermic reactions taking place in the gas phase.

Strand burning samples prepared by pressing AP with different particle sizes are significantly different. Samples prepared from large crystals (>200 μm) display stable combustion in a fairly wide range of pressures (≈ 20 atm), whereas the burning rate in samples prepared from fine AP particles (≈ 100 μm) drastically decreases with decreasing pressure. Flame stability becomes unstable at pressure ≈ 70 atm or higher (Figure 36).

These specific features are substantially different from the effect of the particle size of this oxidizer on the combustion laws for usual high-temperature composite propellants with a fuel. They can be caused by problems associated with topochemical features of thermal conversion of AP. It was found that combustion failure occurs if the total thermal effect of the surface process is negative [740]. A set of equations was derived, the results of which agreed quite well with experimental data on the burning rate and combustion limits of AP with different particle sizes.

Pure AP does not maintain burning at pressures below 2.03 MPa (20 atm). The combustion of AP and AN was studied at atmospheric and sub-atmospheric pressures by increasing initial sample temperature and by adding small amounts of fuels [797]. Measurements were conducted in which the gaseous reaction zone and the burning surface of a propellant sample was photographed as the strand was raised to keep the flame front at the same level. The effects of the oxidizer particle diameter on decomposition and burning rates were investigated by using propellants containing fine oxidizer particles and propellants containing coarse particles. It was found that the diameter of AP particles influenced the decomposition rate more than that of AN particles. Both the decomposition and burning rates were increased when the AP particle diameter was decreased (see [66, 798] also).

5.4 Single Crystal Linear Burning Rates

Burning rates can be measured more reproducibly with single crystals than with pressed grains. Growing large high-quality single crystals of AP from solution is difficult because it requires pure solutions and precise control of supersaturation [799]. Two methods were evaluated for growing large single crystals of AP, the main difference being in the technique of producing a supersaturated solution. One method induced excess nutrients into a system by slowly cooling a saturated solution in a linear manner by 0.05 °C per day, while the other used a thermal gradient to create a flow of solution from a zone in which it was saturated to a cooler zone in which it became supersaturated.

So far, very few AP burning studies have been done using cultured single crystals. The burning rate may depend on the crystallographic direction of the faces of a crystal. This effect depends on the presence or absence of a melt layer on the surface. One would not expect such a dependency for AN, which melts below the flame front. However, with AP, such a dependency may be measurable. Needle-shaped single crystals were grown from an aqueous solution at 310 K (37 °C) to a length of 8 cm and 0.5 to 0.8 cm wide perpendicular to the c -axis [800]. The crystals contained visible inclusions of saturated solution which could not be removed by week-long drying

under vacuum. While it was easy to prepare specimens for burning along the long c -axis, samples perpendicular to c could only be prepared by sawing a needle into short sections and stacking them up and cementing them by surrounding glue. Since the a and b -axis dimensions are similar, one would not expect much difference in the burning rate between a and b . The burning rate at 4.13 MPa (40.9 atm = 600 psia) in the direction perpendicular to the 110 plane was 0.49 ± 0.06 cm/s (avg. of 7 runs) and the burning rate along the c -axis was 0.43 ± 0.04 cm/s (avg. of two runs). Within the accuracy of this test, there was no measurable difference in the burning rate in the different directions. Single crystal burning rates were below those of compressed powder AP pellets.

The deflagration of AP was studied using cleaved sections of large single crystals grown from a water solution [361]. In addition to the preliminary study of the decomposition of single-crystal sections at the relatively low temperature of 483 K (210 °C), detailed photographic observations were made of burning rate and combustion zone characteristics of samples deflagrating in nitrogen atmospheres at pressures from 1.92 to 14.1 Mpa (19 to 140 atm). Burning rates were higher than those obtained by other investigators using pressed granular AP. The LPDL was slightly lower than that reported for pressed material. Burning rates normal to the m face (210) and c face (001) were the same. The burning surface, when looking at quenched specimens, exhibited a pressure-dependent texture quality consisting of ridges, troughs, and craters with heights in the order of 20 μ m. The surface pattern remained relatively constant for burning distances of 103 μ m. Between 1.92 and 4.04 Mpa (19 and 40 atm) the quenched samples had an array of craters that were ~ 150 μ m in diameter with hollow bubbles around the rim. The discovery of trapped bubbles provided convincing evidence of the presence of a **melt layer** on the surface, at least for operating pressures up to 6.06 Mpa (60 atm). At higher pressures, the surface became flatter and the bubbles were smaller. A slightly altered subsurface layer, roughly 15 μ m thick (which was apparently due to crystallographic phase change) was observed in quenched samples. Crystals heated isothermally for several hours at 483 K (210 °C) (without igniting) turned optically opaque, as reported previously. The results imply that even with the high temperatures and high heating rates present in deflagration waves, the decomposition reactions remain slow enough so that a molten state is reached on the surface, with no conspicuous subsurface decomposition of the solid phase at temperatures up to roughly 773 K (500 °C). The presence of contaminants would cause low-melting eutectics on the surface. Similar experiments were made with crystals doped with KMnO_4 or KClO_4 . However, direct observation of the burning surface of AP-based propellants (not just plain AP crystals) with a telescopic microscope seemed to indicate that it was “dry” [801].

It is difficult to measure the temperature on the surface of deflagrating AP crystals, but one can calculate the temperature from measurements of the orthorhombic to cubic polymorphic phase changes taking place as the crystal heats up. The phase change

occurs at exactly 516 K (243 °C). The crystal becomes opaque where the phase change has taken place. Quenching a burning crystal and examining it under the microscope reveals the depth to which the phase change has taken place. Large single crystals of AP have been systematically burned and quenched by rapid depressurization at various pressures from 2.06 to 6.88 MPa (20.4 to 68.12 atm = 300 to 1000 psia). Microscopic measurements of the quenched crystals have been made utilizing polarized light to accentuate the layer of material which undergoes the crystallographic phase transition. It was found that the thickness of this layer is inversely proportional to the linear burning rate of the crystals. Calculations based on heat conduction and energy release indicate that the surface temperature remains constant over a wide range of pressures and the melt layer is at about 833 K (560 °C) [802, 803]. Other thermocouple measurements produced very low surface temperatures of 683 K (410 °C) at 5.05 MPa (50 atm) and 593 K (320 °C) at 10.1 MPa (100 atm). Allowances were made for the variation of thermal properties (heat capacity, thermal conductivity, thermal diffusivity) with temperature. The solid surface temperature in the absence of fuels was virtually independent of the burning rate.

Burning rates and ignition delays of single crystals of AP were measured over a range of pressures between 4.04 and 14.14 MPa (40–140 atm) at 298 K [804]. The single crystal AP burning rates were compared to those of polycrystalline pellets made from “as received” and recrystallized AP. Single crystals burned at a rate that was 25% faster than that of pressed pellets.

The burning rates of AP in various densities, ranging from single crystals to low bulk powders, were measured using high-speed cinematography in a windowed high-pressure bomb under nitrogen [805, 806]. Single crystals were grown from saturated water solutions by gradually lowering the temperature using a programmed thermostat that was accurate to within $\pm 0.001^\circ\text{C}$. The dried single crystals were examined using electrical conductivity and UV absorption measurements and were found to be of high purity. Single crystals were cleaved along natural face boundaries to prepare wafer-like samples for combustion. The crystal dimensions for combustion samples were $5 \times 5 \times 2$ mm ($0.2 \times 0.2 \times 0.08$ in.) At pressures of 6.19 and 10.3 MPa (61.3 and 102 atm = 900 and 1500 psi), burning rates were 0.8 and 1.05 cm/s (0.314 and 0.415 in./s). These data were in excellent agreement with previously published results obtained by Hightower and Price [361]. The crystals were mostly perfect with a few internal voids and cracks. There were enough clear portions in each crystal, however, to get the perfect crystal burning rate. The interpolated burning rate for combustion at 6.88 MPa (68.1 atm = 1000 psia) is 0.84 cm/s (0.33 in./s). Visual examination of the burning surface showed that the product gases are transparent near the surface but, within less than a millimeter, they become a dense white cloud due to product condensation.

In later studies [794], the crystals were cleaved into 1-mm thick slabs. The self-deflagration behavior of single crystals of pure AP can be divided into four

phenomenological regimes that are apparent when the data is entered into a graph and examined. Regime I is the portion of the curve between 2.06 MPa (300 psia) and approximately 5.50 MPa (800 psia), at which the curve has an equation of the form $r_b = Cp^n$ with a burning rate exponent of approximately 0.77. The portion of the curve between 5.50 and 13.76 MPa (800 and 2000 psia), at which the slope is positive but decreasing, defines Regime II. Regime III is the portion that has a negative slope in the pressure range between 13.76 and 27.52 MPa (2000 and 4000 psia). Above 27.5 MPa (4000 psia) is the domain of Regime IV. Burning rate measurements were taken at pressures between 2.06 and 42.66 MPa (300 and 6200 psia) and represented data included: (1) deflagration rates as a function of pressure for the AP crystals, (2) combustion characteristics as seen using high-speed cinephotography, and (3) surface and subsurface characteristics of quenched samples as observed under the SEM.

It was proposed that exothermic condensed-phase reactions occurring in a liquid melt layer at the surface of AP, coupled with exothermic gas-phase reactions, are responsible for the steady-state deflagration of AP in the pressure regime between 2.02 and 10.1 MPa (20 to 100 atm) [807–809].

The deflagration behavior of pure single crystals of AP can be divided into four phenomenological regimes. This is based on experimental data which includes the deflagration rate as a function of pressure for the AP crystals, the combustion characteristics as seen using high-speed cinemicrophotography, and the surface and subsurface characteristics of quenched samples as observed under the SEM. From these data, the energy transfer mechanism for each regime can be inferred. Pure AP doped with 0.05% K^+ produce burning rates very similar to those reported by others who were using AP of dubious purity [810].

The strand burning rates of AP were compared to those of ADN, RDX, HMX, CL20 (=HNIW), and HNF [811]. AP samples used for this study included large high-purity single crystals as well as pressed pellets. The AP single crystals were cleaved to approximately $1\text{ cm} \times 0.5\text{ cm} \times 0.2\text{ mm}$ size samples. Pellets from various powders of AP were pressed at internal die pressures of 335 MPa with a dwell time of about 30 minutes. The densities of the resulting pellets were 99.2–99.4% of the theoretical maximum density. There was no difference in burning rates between the pressed pellets and single crystals as long as high-purity AP was used in the pellets. Only data for ultrapure AP are presented here.

The AP self-deflagration rate data at three initial temperatures (298, 373, and 423 K) over the pressure range of 2.16–10.3 MPa are shown in Figure 37. One should note that the spacing between the burning rate curves at different temperatures is not uniform. The increase in burning rate, and thus temperature sensitivity, becomes greater with increasing temperature.

In these experiments, the LPDL for pure AP at ambient initial temperature was approximately 2 MPa.

5.5 Lower Pressure Limits for the Deflagration of Ammonium Perchlorate

Solid propellants, or oxidizers by themselves, have a lower pressure limit below which stable burning is not sustained. These limits have been determined for AP by itself (no fuel or binder added), and also with or without doping the AP with various catalytic or inhibiting additives. The lower pressure limit is also dependent on the temperature of the sample prior to ignition but is not very dependent on the strand geometry. The lower limit is encountered due to self-cooling. This is mainly due to a loss of radiant heat from the burning surface of the solid, per unit mass burned, which increased as the pressure was lowered. A critical value of the activation energy exists. Below this value the rate of heat generation is less sensitive to surface temperature than is the rate of heat loss. A solid monopropellant with a sufficiently large heat release rate should theoretically be able to burn down to zero pressure.

Table 20 is a summary of experimental studies of the lower pressure limits for AP deflagration in strand burners.

The decomposition flame of AP has been studied by measuring burning rates, flame temperatures, and perchlorate surface temperatures [814]. At pressures below

Table 20: Results of experimental studies of the lower pressure limits for AP deflagration in strand burners.

Pressed strand cross section mm	AP condition	Density g/cm ³	Particle size μm	Lower pressure limit		References

that at which deflagration of pure AP is self-sustaining, combustion was maintained via minor additions of fuels or by preheating the salt. Most people developing models for AP combustion assumed a smooth phase boundary between the condensed phase and the gas phase. However, it was observed that particles get ejected into the reaction zone, a process which would substantially increase the burning surface area. The reaction that drives the particle ejection may be the LTD of AP, which usually stops after 30% weight loss has taken place. Particles impacted and were collected on cold witness plates inserted 0.5 to 1 cm above the burning surface. This observation may explain the dependence of burning rate on particle size.

Tests with pellets pressed to different densities between 1.51 and 1.92 g/cm³ revealed that the lower pressure limit decreases with increasing density. On the other hand, slightly compacted samples of different particle sizes revealed that the lower pressure limit drops with increasing particle size. It is thought that the flame front can better penetrate between the coarser particles. Water content up to 0.7% had little effect on the lower limit of burning but pressed pellets with 2% H₂O could not be ignited even at pressures up to 15.15 MPa (150 atm) [798].

The lower pressure limit for AP strand burning is quite sensitive on the initial temperature of the pellets. The lower pressure limit of AP single crystals has been determined by establishing a known temperature gradient in the crystal and then igniting it from its warmer end. Deflagration then would only propagate to a certain depth into the pellet and extinguish at a known temperature [817–819]. The pressure was adjusted so that the flame would not propagate through the entire solid and the length of the sample remaining unburned determined the limiting solid temperature corresponding to the set pressure. The AP single crystal deflagration rates were measured using high-speed motion photography and were essentially the same in helium and nitrogen ambient atmospheres. In direct contrast to the catalytic effect of KMnO₄ on AP thermal decomposition, a preliminary study revealed that 0.4–2.0 mol-% KMnO₄ isomorphously substituted into the AP crystal lattice prevented deflagration from occurring [820].

Quenching of AP combustion is not just an academic exercise. The lower pressure limit of AP burning has practical significance for thrust termination of missiles that need to impart less than the full motor total impulse. Applying laminar flame theory to an adiabatic, steady-state one-dimensional AP single crystal surface with Arrhenius temperature dependence for the condensed phase gasification and the gas phase reactions allows one to predict a LPDL only when the activation energy of the overall surface reaction is less than half the activation energy of the gas phase reaction [821]. Applying this model to AP, the extinguishment limit can be predicted if one assumes that the activation energy of the condensed phase gasification is 41.8 kJ/mol (10 kcal/mol) and the activation energy of the gas phase reaction is 125 kJ/mol (30 kcal/mol).

The lower pressure limit of pressed AP pellets may be quite dependent on the method used for mounting the pellets. Two different mounting techniques were used in an investigation on the deflagration of pressed AP [822]: In the first, tubular sam-

ples were cemented into the burner with epoxy resin which inhibited all of the grain surface except the inner perforation. In the second, the grains (either tubular or disk shape) were press-fitted into metal sleeves that were subsequently fitted into the motors. It was noted that whatever little combustion occurred at the interface between the AP and the epoxy mount was sufficient to sustain combustion down to 303 kPa (3 atm) while the metal-mounted ones extinguished at 2.32 MPa (23 atm).

The lower pressure limit of pressed AP pellets increased with the bulk density of the pellets, burning surface area, and the initial sample temperature [816]. It decreased when coarser AP powder was used to make the pellets. The lower pressure limit was typically reached when the burning rate dropped to 0.17–0.19 cm/s, regardless of the other variables involved. The addition of 5–30% CuO lowered the lower pressure limit from 2.02 to 0.02 MPa (20 to 0.2 atm). Nir also studied the combustion of AP/Al and AP/B mixtures [816]. In summary, it was concluded that:

1. The burning rate of AP does not approach zero as the pressure limit is approached. For samples with different physical parameters, the pressure deflagration limit is obtained approximately for the same mass burning rate (0.17–0.19 cm/s).
2. The LPDL decreases with increasing the strand density, the burning surface area, and the sample initial temperature (see Figure 38 for two different burning surface areas: 10 and 133 mm²).
3. The internal structure of an AP pellet compressed for several hours is different from that of a pellet compressed briefly. In the first case the structure is more uniform and homogeneous and the volume of the voids is reduced. Heat losses due to voids are then less important and AP deflagration can be maintained down to near 2.02 MPa (20 atm).
4. AP particle size determines the LPDL. It decreases as the particle size increases. When the mean initial size of AP particles exceeds 1 mm, the pressure limit of the strand is slightly higher than that of a large single crystal.

The pressure limit is reduced with increasing strand density. The solid lines in Figure 38 is the result of applying the equation

$$P_L = \frac{K}{e^{\alpha(T_0 - T^*)}}$$

where P_L is the lower pressure limit, K is a constant, $\alpha = 0.003^\circ\text{C}^{-1}$ is the temperature coefficient, $\alpha = 2\beta$, T_0 is the initial sample temperature, T^* is a reference temperature, and the particle size ϕ is 1000 μm . It can be seen that the LPDL, P_L , changes linearly with the strand density, ρ . At 20 °C, for $\rho = 1.50 \text{ g/cm}^3$, one finds $P_L = 32 \text{ atm}$ whereas with a higher density of 1.92 g/cm^3 , the pressure limit is only 22 atm. This value is in excellent agreement with that obtained by other authors.

The addition of 2–5% of copper, cobalt, or manganese compounds as catalysts lowered the lower pressure limit all the way down to atmospheric pressure [823]. The following efficiency series for 5% additives of metal oxides for AP combustion at atmo-

Figure 38: The lower deflagration limit of AP as a function of initial temperature. (Reprinted and modified from [816], © 1973, with permission from Elsevier; permission conveyed through RightsLink.)

spheric pressure was reported as: $\text{Cu}_2\text{O} > \text{CuO} > \text{MnO}_2$ at $T_0 = 20^\circ\text{C}$ and $\text{Cu}_2\text{O} > \text{CuO} > \text{MnO}_2 > \text{Co}_2\text{O}_3 > \text{ZnO}$ at $T_0 = 100^\circ\text{C}$. At the same time, Fe_2O_3 , NiO , Ni_2O_3 , Cr_2O_3 , CdO or MgO did not ensure stable combustion under these conditions [824].

Pure AP single crystals could not sustain a flame at pressures lower than about 2.06 MPa (300 psia) [794, 825]. The AP burning behavior could be readily divided into four pressure range regions. In pressure region I between about 2.4 and 5.5 MPa (350 and 800 psi), a steady and positive burn rate pressure exponent was exhibited. Pressure region II in the 5.5 to 13.8 MPa (800 to 2000 psi) range had a positive burn rate pressure exponent that gradually declined. Near 13.8 MPa (2000 psi) an abrupt change to a strongly negative burn rate pressure exponent set in that had a lessening negative exponent until bottoming out near 27.6 MPa (4000 psi) (Region III). At about 27.6 MPa (4000 psi) in pressure region IV the burn rate pressure exponent reversed this trend at increasing pressure and reached positive values, which increased to exceed exponent values well above 1.0. The high exponent trend continued up the test limit of about 42.7 MPa (6200 psi). Cleaved AP crystals burned fairly evenly at pressures near

65.9 MPa (1000 psi). However, AP crystals burned quite unevenly in the 13.8 to 27.6 MPa (2000 to 4000 psi) Region III.

The lower pressure limits of AP and KClO_4 /AP mixtures with organic fuels with and without catalysts were determined in a closed bomb [826]. Predicting the lower pressure limit for AP strand burning using theoretical models has been attempted, however, only with limited success (see Section 5.17).

A unified theory was proposed to explain the various aspects of the combustion of AP, which has been separately treated up to now via burning rate, LPDL, and ignition using a single framework model [827]. The model, on the basis of which the theory was formulated, incorporated the experimentally observed micro-structure of the burning surface of AP, which provides an intermediate heat sink in an overall adiabatic system. The theory explained the existence of the LPDL of AP, which has eluded previous attempts at theoretical explanation. The model accurately predicted the variation of the limiting pressure with an initial solid temperature and also the nearly constant burning rate at the LPDL, regardless of the initial solid temperature. A comparison of the theory and experiments for the LPDL and burning rate of AP indicated that the same reaction mechanisms prevail during deflagration and near the pressure limit and that the extinction is due to heat loss rather than due to a change in reaction mechanism. The rates of the gas-phase reactions were found to be well-represented by second-order overall kinetics.

The type of insulation applied to inhibit burning along the sides of the strands and the modes of heat loss play a critical role in AP combustion. They also determine the LPDL of AP itself and the steady-state burn rate of AP at higher pressures. The common use of silica-filled poly(dimethylsiloxane) grease to prevent heat loss from the sides of the pellet and the ignition methodology influence the strand burning results. Using a slow depressurization method, wherein the LPDL was independent of ignition transients, the LPDL of pure AP was found to be 1.4 MPa (14 bar) [828]. The burn rate of well-insulated pure AP at 7 MPa (70 bar) under near adiabatic conditions was found to be 10.66 mm/s, which was much faster than burn rate data reported in the literature. The pressure exponent for this case was 0.71. This result completely changed the current understanding of AP combustion and called for a new set of parameters to be developed to predict the results obtained with insulating silica-filled grease on the sides of the strands. Using the same set of parameters, along with a heat loss model for the case when there was no silica grease applied, the predictions were in reasonable agreement with the experimental data reported in the literature without any silica-filled poly(dimethylsiloxane) grease on the sides of the AP pellet.

5.6 Upper Pressure Limits for the Deflagration of Ammonium Perchlorate

Some investigators (Levy and Friedman [813]) have observed an upper pressure limit for the deflagration of AP near 25.2 MPa (250 atm). In an attempt to explain this, re-

searchers have pointed to changes in the heat transfer mechanisms between the flame front and the subliming surface but others have not confirmed this observation. The existence of an upper pressure limit has been questioned by other investigators. Differences in upper limit measurement results have been blamed on different methods of containment used by several investigators. For instance, some experimenters pressed the AP powder into PMMA tubes.

It has been suggested that the upper pressure limit is due to small sample diameters. In experiments by Glazkova [815], the 5-mm diameter strand had an upper pressure limit of 27.3 MPa (270 atm). However, with 7-mm diameter strands, no upper limit was observed within the pressure capability of the apparatus (34.3 MPa = 340 atm).

The deflagration characteristics of pure AP strands have been investigated by means of a closed-bomb strand burning technique at pressures between 6.88 to 158 MPa (68.1 to 1566 atm = 1000 to 23000 psi) [829]. The data was in general agreement with vented-chamber AP burning-rate data obtained by other investigators at pressures between 6.88 to 34.4 MPa (68.1 to 340 atm = 1000 to 5000 psi). There are two regimes with a transition around 30.3 MPa (300 atm) with pressure exponents of 0.25 and 1.75. At pressures above 34.4 MPa (5000 psi) (the pressure limit of previously reported studies), a marked increase in pressure dependence of the linear burning rate occurred. It is postulated that the observed increase in burning rate results from an increased burning surface area, i.e., surface break-up, under the action of the very high pressures existing in the closed bomb, forming new cracks and pores or by enlarging existing cracks and pores. A geometrical model was proposed which considered the accelerated burning process as a development of micro-cracks that form into conically-shaped burning surfaces, the area of which depends upon the pressure. The model is in good agreement with the experimental burning-rate data and with the pressure versus time data for individual burning-rate experiments at pressures above 34.4 MPa (5000 psi). The steepening of the temperature gradient with increasing pressure causes thermal stresses in the crystals.

5.7 Isotope Effects on the Burning Rate of Ammonium Perchlorate

In a study of deflagration of NH_4ClO_4 and ND_4ClO_4 , it was noted that visual changes always began in the bulk of the crystals and not on the surface [483]. In both cases decomposition stopped when the degree of conversion was about 30%, at which point porous products formed which underwent the same phase transition as the parent single crystals. Thermal decomposition of the deuterated sample was slower, the volume fraction of pores appeared to be lower, and the sample had a small quantity of "snow" on the surface. These isotope effects were blamed on proton transfers at the intersections of dislocations in the bulk of the crystals. The rate would be different for the movement of H^+ as opposed to D^+ ions.

5.8 Temperature Profiles in Burning Ammonium Perchlorate

The current section on temperature profiles in burning AP deals with phenomena very similar to those discussed in a later section based on the surface temperature of burning AP. There is some overlap between these two sections and we may very well have combined the two to create one section, however that would have created an unwieldy large section.

The temperature distribution in burning AP was studied with the aid of thin thermocouples [830–832]. AP was compressed into 7 mm pellets with a bulk density of 1.93–1.94 g/cm³ and ignited in a constant pressure bomb at 3.04–35.4 MPa (30–350 atm) in a nitrogen atmosphere. Above 15.2 MPa (150 atm), a regular temperature oscillation in the gaseous phase with a period of about 50 μ s and an amplitude of up to 773 K (500 °C) was noted. The pressure range of 16.2–35.4 MPa (160–350 atm) was called the region of unstable burning. In the region of stable burning (4.05–15.2 MPa = 40–150 atm), an increase in the total heat emission in the gaseous phase was observed, whereas the heat emission in the condensed phase decreased with an increase in pressure. At 15.2 MPa (150 atm), the heat emission was 80 cal/g, which is a critical lower limit. This was the threshold separating the regions of stable and unstable burning. Below 80 cal/g, burning was quenched. It was assumed that during burning catalysis of the decomposition of AP took place on the surface. This was caused by reaction products and active centers passing from the flame zone to the surface of the condensed phase. This assumption probably explains the mechanism by which the gaseous phase controls the decomposition of the condensed phase. The maximum burning temperature first increased with pressure, passed through a maximum value at 1333 K (1060 °C) and 10.1–15.2 MPa (100–150 atm), and then decreased, although the pressure continued to rise. The decrease of burning rate with increasing pressure is unusual and has been explained as a catalytic effect exerted by the decomposition products diffusing from the flame front to the burning surface. The reaction takes place in the gas phase and not in the condensed phase (see [833, 834] also).

The emission spectroscopy of burning AP can provide information about the reacting species in the flame front [835, 836].

Measurements of temperatures and the concentration profiles of reacting components in an AP flame provide at least some of the data needed to verify or dispute previously unproven combustion models established by various other investigators [837].

Based on numerous thermocouple-aided experimental studies on the combustion of different energetic oxidizers like AP, IN, or ADN, it has been shown that a salt in the condensed phase can be heated up to its dissociation temperature. In contrast to the gas-phase model, the condensed-phase burning rate model has an energy limitation. In condensed-phase reactions the burning rate increases at the expense of surface temperature increase with pressure. A situation can arise where the heat effect of en-

ergetic material decomposition is no longer sufficient for warming-up the decomposing substance to the surface temperature. This induces an instability of combustion and burning rate oscillations [838, 839].

The surface temperature in the combustion wave of AP, as well as in ADN, HNF, and AN, is controlled by a dissociation process, similar to that postulated for other onium salts [840].

5.9 Effects of Initial Temperature on Ammonium Perchlorate Burning Rates

The dependence of burning rate of solid propellants σ_p is typically expressed by the equation:

$$\sigma_p = \left(\frac{\partial \ln r}{\partial T} \right)_p = \frac{1}{r} \left(\frac{\partial r}{\partial T} \right)_p$$

This same equation applies to the burning of AP by itself in the absence of combustibles, and with or without the addition of catalysts.

The effect of initial temperatures on the rate AP combustion at initial temperatures in the range of 297–423 K (20–150 °C) was investigated at pressures up to 35.35 MPa (350 atm) [841, 842]. The purpose of this work was to explain the earlier observed anomalies of combustion characteristics and to explore the possibility of eliminating the upper explosion limit and of increasing combustion stability by increasing initial temperature. The burning rate of compacted 7 mm diameter samples increased, the lower explosion limit decreased, and the region of stable combustion was extended when the initial temperature was increased. Unstable combustion of a different kind appeared at an initial temperature of 448 K (175 °C). The minimum temperature coefficient of the burning rate coincided with the maximum burning rate at 15.15 MPa (150 atm) in the region of stable combustion. Heat evolution in the reaction zone of the solid phase and conductive heat transfer from the gas phase into the solid phase do not depend on the initial temperature and actually decrease with increasing pressure. The observed anomalies were believed to be the result of combustion inhibition caused by water which was accumulated in the reaction zone.

Uncoated AP in the shape of 7 mm pellets compressed to crystal density was burned at a constant pressure. The initial temperatures ranged between 293–423 K (20–150 °C) and pressures were up to 35.5 MPa (350 atm) [843]. As expected, an increased initial temperature increased the combustion velocity, lowered the lower pressure limit, and raised the upper limit. The critical pressure, below which the burning rate decreases and deflagration become pulsating, rose from 15.2 MPa (150 atm) at an initial temperature of 293 K = 20 °C to 20.27 MPa (200 atm) at an initial temperature of 323 K = 50 °C and to 25.33 MPa (250 atm) at an initial temperature of 373 K = 100 °C.

The temperature coefficient β of strand burning rates of easily gasified propellants is expressed by

$$\beta = \partial \frac{\ln r}{\partial T_0} = \frac{E_a}{2RT_c}$$

where r is the burning rate, E_a is the activation energy of the gas phase reaction and T_c is the combustion temperature. The effect of pressure, p , on the temperature coefficient β of the combustion rate of the condensed energetic materials were analyzed and compared to experimental data obtained for AP [844]. The theory demonstrated that a low p , β is markedly dependent on the initial temperature, T_0 , and only slightly dependent on the activation energy E_a of the decomposition reaction and the activation energy of evaporation E_{vk} . At high pressures, the increase in β is determined mainly by E_a and E_{vk} . While at low pressures, β increases with T_0 , at high pressures, β decreases with increasing T_0 . The theory was confirmed by published experimental data on strand burning of AP.

5.10 Counterflow Diffusion Flames Supported by Ammonium Perchlorate Decomposition

This technique for studying the decomposition processes on the surface of AP crystals or AP slabs is similar to a sandwich burner, except that the fuel is not in solid form but enters the reactor as gas and impinges on the solid oxidizer in a direction opposite to the flow of oxidant. One can thus vary the oxidizer : fuel ratio during the experiment by throttling the fuel flow as in an inverse hybrid rocket engine. A two-dimensional set of governing equations for modeling the structure of AP counterflow diffusion flames (in which the products of AP combustion are flowing against a methane fuel stream) was used to formulate a detailed transport, finite-rate chemistry system for the temperature, velocity, and species mass fractions of the combined flame system [845–847]. The two-dimensional problem can be reduced to a one-dimensional boundary value problem along the stagnation point streamline through the introduction of a similarity transformation. The results of this model were compared with a series of experimental measurements in which the temperature was measured with radiation-corrected thermocouples and the OH rotational population distribution. Several important chemical species, including OH, CN, NH, NO, CH₄, and O₂ were measured with planar laser-induced fluorescence (PLIF), emission spectroscopy, and Raman spectroscopy. Both the model and the measurements revealed a multi-stage structure within the counterflow system, comprised of an AP decomposition flame (above and close to the AP surface), followed by an AP-products/methane diffusion flame. Both flame zones lie to the AP side of the stagnation plane.

This concept is similar to sandwiching a slab of AP between two layers of combustible solid fuels or sandwiching a layer of solid fuel between two blocks of oxi-

dizer. In either case, the burning rate is influenced by mass transfer and its diffusion limitations.

Other pyrolysis techniques involve convective heating using an impinging jet from a gas rocket and also surface-temperature measurement using IR radiometry [133]. An apparent activation energy of 92 kJ/mol (22 kcal/mol) was reported for AP with surface temperatures between 698 and 848 K (425 and 575 °C) and with regression rates between 0.002 and 0.04 cm/s. The overall pyrolysis mechanism was proposed to be a rate-controlled dissociative sublimation. The technique used allows for consideration of partial pressures and heat fluxes at the pyrolyzing surface in addition to measurements of regression rates and surface temperatures during pyrolysis.

The burning of AP in composite solid propellants was simulated in a counterflow burner in which the heat feedback from the hot, inert, opposing, and stagnating flow stabilized the AP monopropellant flame above a pressed AP pellet [848]. The heat feedback mechanism was investigated using thermocouples and a heat-flux meter. The regression rate data were analyzed using activation-energy asymptotics and the overall activation energy of the AP flame was found to be 59.8 kJ/mol (14.3 kcal/mol). The typical burning structure of AP at 101 kPa (1 atm) consisted of a 5000- μ m thick thermal gradient layer in the solid phase and a 500- μ m thick AP flame in the gas phase. Temperature measurements using fine wire thermocouples showed the surface and flame temperatures to be 810 and 1220 K, respectively.

Although AP does not normally self-deflagrate at pressures below 1.376 to 5.504 MPa (200 to 800 psia), it was possible to stabilize a counterflow diffusion flame above a deflagrating AP pellet even at 1 atm. A nearly perfect planar flame structure could be imaged, measured, and compared to computational model predictions [849–851] (Figure 39). Methane or ethylene was used as fuels. Fuel mixtures can be selected to simulate the decomposition products of various binders, or a single fuel can be used if one wants to simplify the kinetics and compare experimental and theoretical results. The fuel exit orifice was 7.7 mm and the AP pellet diameter was 10 mm. Both the fuel orifice and the AP pellet were surrounded by annular nitrogen shrouds (25 mm).

The fuel flow rate can be controlled using a flow meter and a needle valve, however, the oxidizer flow rate is determined by using the rate of ablation of the AP. The AP regression rate was 0.11 mm/s. The burning AP surface was kept at a constant distance from the fuel orifice by pushing the grain from below into the reactor with a threaded rod drive rotating at variable rpm. Flame temperatures were measured using thermocouples and also spectroscopically via OH rotational planar PLIF. The computational model assumed a laminar counterflow flame stabilized in the vicinity of the stagnation plane. The AP surface temperature was assumed to be 825 K. The model predicted an AP decomposition flame above the AP surface followed by a fuel/AP-products diffusion flame, in agreement with experimental observations.

Figure 39: Counterflow burner for AP regression rate studies. (From [850].)

5.11 Concurrent Flow Diffusion Flames Supported by Ammonium Perchlorate Decomposition

Instead of impinging the fuel gas on an AP surface in a direction opposing the flow of reaction products, a flow of combustible gas can be passed through a PAP grain and lit at the surface. In this arrangement, the direction of the incoming gas and the outflowing reaction product is the same. The porous plugs were made from slightly compressed powder which was moistened by moist air and then dried to bond into a coherent cylinder.

If methane is flowing through a PAP grain and ignited, the regression rate of the oxidizer is of the same order of magnitude as that in composite propellant grains [852, 853]. The particle sizes used were 74–105 μm , 149–210 μm , and 297–420 μm . Smaller particles resulted in higher burning rates. The burning rate was linearly dependent on pressure at 25.2 kPa (0.25 atm) and this dependence increased to a fractional power with increasing pressure. It was concluded that the vaporized products were not in thermodynamic equilibrium with the solid, the rate of AP surface regression was not related by an Arrhenius function to the surface temperature, and the final flame zone did not supply the major fraction of the heat conducted back to vaporize the AP. This

heat came mostly from the AP decomposition flame augmented by the back diffusion of a small amount of fuel. The logarithm of the total mass consumption plotted against the reciprocal of the final flame temperature produced a straight line with a slope corresponding to an activation energy of 92 kJ/mol (22 kcal/mol). The porous burner technique might even find an application in hybrid motors where the regression rate can be increased by almost two orders of magnitude.

Instead of bonding the AP particles together by moistening them, others have created PAP grains by using glue made of PMMA in acetone. Burning rates of PAP grains prepared in this manner and perfused by fuel gases were measured at atmospheric pressure [854, 855]. The AP regression rates increased in the order $\text{H}_2 > \text{C}_2\text{H}_2 > \text{C}_2\text{H}_4 > \text{CH}_4$ and occurred near stoichiometric O:F ratios. Except with NH_3 , the maximum rate was achieved only with fuel-lean mixtures.

A variant of the fuel flow through a PAP pellet is the combustion of spherical AP particles suspended on a wire mesh in a flow of combustible gas [856, 857]. Small (6–15 mm diameter) spheres of AP were placed on a wire mesh through which the gas entered the chamber and was then ignited using a hot wire. The sphere burned evenly on all sides. Depending on the fuel, a decomposition flame near the surface and a diffusion flame surrounding the decomposition flame was observed. When ammonia was used as the fuel gas, the sphere was enclosed by concentric flame zones. Results showed that the diffusion flame alone controls the sphere combustion rate. The parameters investigated in that study were the gaseous fuel flow velocity, type of fuel gas, chamber pressure, and the initial AP spherule diameter (with and without the addition of catalysts to the AP prior to its forming into microspheres) (see [858] also).

Most AP combustion studies have been conducted using stagnant or slow flow over the AP solid surface. However, this is now what is happening in an actual rocket motor, where combustion products flow over the burning surface and cause erosive burning. The erosive burning of AP by itself has not been thoroughly examined. The effects of turbulence on the mean reaction rate and on reaction rate correlations (combustion-turbulence interaction) were analytically investigated with applications to the erosive burning of AP [859]. The analysis indicated that regions of both decreased and increased reaction rate and turbulent diffusivity can exist in the flame zone. Further to this, it was found that the decreased reaction rate may account for the decrease burning rate (“negative erosion”) observed for some propellants. The results showed that: (a) although significant changes in reaction rate and turbulent diffusivity profiles are obtained, no appreciably decreased burning rate was predicted for AP using either combustion model; (b) for both normal and erosive burning, the flame height produced by some models is substantially greater than that produced by other models; and (c) as a consequence of the disparate flame heights, a much greater susceptibility of AP to erosive burning can be predicted. The erosive burning response of propellant can be used in determining its relative flame height.

5.12 Sandwich Burning Supported by Ammonium Perchlorate Decomposition

The burning of alternating layers of oxidizer and fuel in a sandwich burner can give valuable information on the mechanism of heterogeneous propellant burning and on the effects of various additives (mostly burning rate catalysts) that could not be obtained by processing the oxidizer and the fuel into a thoroughly mixed propellant grain. The general method of sandwich burning will be discussed in future volumes dealing with solid propellants. That section describes the experimental technique and its analytical interpretation in general, regardless of which oxidizer is used in slab form. The current section describes sandwich-burning experiments specifically with AP.

Catalysts were incorporated into AP oxidizer sandwiches with oxidizer sections laminated between thin layers of CTPB as a binder [860]. Catalysts investigated were copper chromite and Fe_2O_3 . Burning of the sandwiches at 4.23 MPa (600 psig) and 13.86 MPa (2000 psig) was recorded using cinematography at 1600 frames/s and 2:1 magnification. Copper chromite was a more active catalyst than Fe_2O_3 and appeared to more effectively promote AP deflagration, catalyze gas-phase reactions, and promote gas-phase reactions in cracks between the solid fuel and the binder without modifying the pyrolysis mechanism of the binder. Fe_2O_3 produced similar effects but inhibited AP deflagration at 4.23 MPa (600 psig). Eventually, these tests were extended to higher pressures of up to 22.11 MPa (3200 psig) [861].

Combustion experiments of sandwiches made of alternating layers of AP and a matrix of AP particles in a polymeric binder performed over an expanded pressure range from 0.34 to 13.8 MPa (50–2000 psig) resulted in sandwich burning rates with plateaus in the 6.9–13.8 MPa (1000–2000 psig) pressure range (but only for specific lamina thickness) [862]. Lamina thicknesses were varied over a wide range. These plateaus were correlated with similar plateau (mesa) trends in the burning rates of composite propellant formulations with bimodal oxidizer particle size distribution. The dependence of the sandwich burning rates on the matrix lamina thickness and the quenched surface features were examined to explain the plateau burning rate trends. The results indicated that the two-dimensional coupling of heat feedback from the hot near-surface parts of the oxidizer/fuel diffusion flamelets is diminished at higher pressures due to their greater proximity to the burning surface and the corresponding shrinking of their lateral extent. The 2003 publication [862] is an extension of past works in the pressure range of 2.07–6.9 MPa (300–1000 psig), wherein sandwiches with the middle lamina made of (1) pure binder lamina, (2) an uncatalyzed matrix of fine AP and binder, and (3) a fine AP/binder matrix with the addition of a nanoparticle-size iron(III) oxide burning rate catalyst, were tested.

Some AP formulations not only went into a mesa-burning mode but extinguished altogether in the mid-pressure range. The mid-pressure extinction of AP matrices with monomodal particle size distribution and HTPB binder was observed in the pressure range around 2–5 MPa [863]. Quenched surfaces (self-extinguished or intentionally interrupted during burning) of all the three types of samples were analyzed using an

SEM. The burning history of the samples was captured with a high-speed digital camera. The results indicated the prevalence of intermittent burning of the matrixes as the pressure was varied across the boundary between continuous burning and self-extinction (burn/no-burn boundary) of the matrixes.

5.13 Oscillatory Combustion During Ammonium Perchlorate Deflagration

Combustion instability has plagued solid rocket motors since they first came into use. It has been attempted to suppress combustion instability by either adding additives to the propellant or by using proper grain and motor geometry.

AP-based propellants are susceptible to combustion instabilities. Even AP by itself is not an exception to this. In an investigation exploring the contribution of AP deflagration to the amplification of pressure waves during combustion instability, 17 firings were made at pressures ranging from 1 to 60 atm. [822]. Oscillatory combustion was observed only in two of the tests. The occurrence of oscillatory behavior at low frequency may be related to the high-pressure exponent.

There are two regimes of AP burning: a stable regime at 4.04–15.15 MPa (40 to 150 atm) and an unstable regime at 16.16–35.35 MPa (160 to 350 atm). Between 16.16 and 35.35 MPa (160 and 350 atm) temperature oscillations were observed in the gas phase. The oscillations had a period of $\sim 50 \mu\text{s}$ and an amplitude of 500°C while measuring temperature profiles of burning AP pellets and the reaction space above it [831].

The mass burning rate versus pressure curve for unconfined pure AP has a region where the combustion starts pulsating and becomes unstable. Strangely, in the range 16.15 to 25.25 MPa (160–250 atm), the burning rate falls with pressure. However, in the range of 25.25 to 50.5 MPa (250–500 atm), it remains constant. Only above 50.5 MPa (500 atm) does it increase with pressure [864].

5.14 Ammonium Perchlorate Combustion at Very High Pressures

The deflagration rate of pure AP demonstrates an unusual “mesa burning” trend in the 13.8–27.56 MPa (2000–4000 psi) pressure range. This observation has been reported not only for pure single crystals of AP but also for pellets pressed from granular high-purity AP. The mesa burning trend is extremely sensitive to the presence of impurities, as can be shown by burning AP single crystals that were isomorphously doped with known amounts of impurities. The onset of the mesa burning trend shifts to higher pressures at higher initial temperatures of the sample (pressed pellets of AP). The mesa burning rate trend is associated with a transition from steady regression to a rather complex mode of deflagration. This is characterized by the following features: **(1)** macroscopically irregular surface regression, **(2)** locally intermittent flamelets on the same spatial- and timescales as the irregularities in surface regression, and **(3)** an

extraordinarily complex topochemistry on the surface of quenched samples in which locally recessed areas of the overall burning surface consisted of arrays of parallel needles 100–200 μm long and 5 μm across. The exact physicochemical mechanisms involved in this mode of deflagration, the explanation for the mesa burning rate trend, and interpretation of the corresponding surface features were difficult to explain. For this reason, the behavior has been called “anomalous” [865].

The rate of self-deflagration of AP decreases sharply with an increase in pressure between 13.8 and 27.56 MPa (2000–4000 psi), depending on the initial temperature and purity of the sample. This is associated with sporadic burning and the formation of “needles” in regions of accelerated regression on the surface of self-deflagrating AP in that pressure regime. SEM observations of the surface of quenched and partially burned samples of both single crystals and pressed pellets of AP deflagrating at different pressures in the 2.75–15.82 MPa (400–2300 psi) range were made in order to obtain a better understanding of high-pressure phenomena [866]. It was noted that needle formation could potentially be an artifact of the method used to quench the burning of samples at pressures below 13.8 MPa (2000 psi), which is contrary to previous results. There are multi-dimensional heat transfer processes taking place at the burning surface that may cause the formation of needles.

The multi-dimensional combustion front of AP was investigated at a pressure range of 2.52–10.1 MPa (25–100 atm) where the combustion of AP is usually considered to be stable [867]. The surface of the samples extinguished by three different methods was examined under the microscope in order to determine the combustion mechanism.

An analysis was conducted of the surface of burned AP samples quenched by a sudden pressure drop or by an injection of coolant spray onto the burning surface, as well as an analysis of samples extinguished due to their diameter being close to the quenching diameter. This revealed that at pressures that lead to steady burning rates (2.5–7.0 MPa), the burning surface is non-planar and non-uniform but features a cellular hotspot-type pattern [868]. Hotspots emerged and disappeared at the burning surface. Their diameter and depth were pressure-dependent and the maximum diameter of hotspots depended on the pressure. It exceeded the characteristic thickness of the heat conduction zone by about two orders of magnitude but was smaller than the critical quenching diameter by a factor of 1/2. Measurements of the electric conductivity of the surface layer and of the local luminosity of the flame revealed the existence of pulsations of approximately the same frequency. The period of these pulsations was close to the lifetime of hotspots.

5.15 The Effect of Additives on the Strand Burning Rates of Ammonium Perchlorate

The addition of additives to AP may increase or decrease its burning rate. Additives that increase the burning rate are called catalysts. Additives that decrease the burning rate

or inhibit burning altogether are called inhibitors. A chemical that acts as a catalyst in the thermal decomposition of AP does not necessarily have to be a catalyst that actively increases the burning rate of AP by itself or propellants formulated with AP. A catalyst that accelerates the deflagration of pure AP, may fail to do so when AP is incorporated in a binder to make a propellant. The effect of catalysts on both the burning rate and the lower pressure limit is a subject that continues to lack an explanation yet has considerable data regarding it. Burning rate increasing additives tested with AP are mostly transition metal oxides or transition metal metallocene complexes. Because it is easier to study thermal decomposition in a DTA or DSC with very small samples than to carry out burning rate measurements, all of these catalysts had been previously studied for their effect on the rate of thermal decomposition of AP. Many will be discussed in subsequent volumes for their effectiveness in changing the burning rates of AP-based propellants. Table 21 gives a summary of burning rate catalysts for AP. One of the most thoroughly studied burning rate catalysts is copper chromite. Several of these studies were conducted where the investigators measured both the effect of additives on the thermal stability (see Section 4.6.8) and the linear burning rate of pressed strands of AP. In some cases, they also determined the lower pressure limit for stable burning. Section 4.6.8 and the current chapters need to be read in context with each other.

It is very difficult to systematically arrange the information on the catalytic or inhibiting action of the various metal oxides. There is not a single study where all oxides were tested side-by-side under identical conditions. Most investigators have studied just a handful of additives and moved on to something else. This makes it difficult to compare results from different investigators. There is a lot of contradictory information in the literature. It seems that other factors (pressure, temperature, particle size of catalyst, amount of catalysts, particle size of AP, other contaminants, moisture, porosity of pressed grains) have dominated over the effects of catalysts and have not always had carefully enough controlled and maintained constants. Singh [869] has attempted to collect information from 68 sources in an effort to summarize the situation as it existed in 1978.

It was surprising to discover that the burning rate of pressed AP pellets varied substantially with the source of the material and depended on how many times it had been recrystallized to purify it. This indicates that the burning rate of AP is very sensitive to contaminants and moisture [870]. The burning rates of polycrystalline pellets of AP from three different sources and with different degrees of recrystallization were measured and compared. The burning rate changed considerably in the first three successive recrystallizations. The data showed that the impurities affected the burning rate, especially at high pressures. Impurities could be removed via recrystallization. It was found that occluded water in AP pellets changed the deflagration rate considerably. These results indicate that one of the causes for the disagreement among different investigators on the burning rate of AP might well be the effect of traces of residual impurities. These were present in the crystals and pellets used in the studies even after purification using recrystallization. The study results also indicated that the nature of

impurities in the “as-received” or recrystallized AP depends on the source of supply. It was also noticed that pressing uniform pellets of reproducible quality is very difficult. Considerable experimental evidence exists which indicates that the distribution of catalysts has relatively little effect on its performance. A mathematical model was developed to calculate the effectiveness factor for surface reactions. This was coupled with surface diffusion on a solid-catalyst surface or bulk diffusion near the burning surface, with discrete adsorption centers. The mathematical model assisted with explaining the experimental data assuming integral-order global reactions.

It is interesting to note that burning rate modifiers used in AP propellants are not effective in potassium perchlorate-based propellants. This supports the idea that the catalysts in AP propellants are active because they catalyze HClO_4 decomposition or NH_3 oxidation.

5.15.1 Effects of Metal Oxide Catalysts on the Burning Rate of AP

There exists a flood of publications on the effect of catalysts on the burning rate of AP either by itself or in a mixture with combustible fuels or binders. In addition to measuring the burning rate as a function of pressure, some investigators extended the experiments to the lower pressure limit, beyond which burning ceases and the flames extinguish. Catalysts accelerate the burning rate by projecting from the surface into the thin gaseous reaction zone and producing local acceleration of reaction rate. Very low concentrations of a catalyst, however, acts primarily to reduce flammability by raising the lower pressure limit, because the catalyst increases the emissivity of the burning surface and, hence, the rate of radiant heat loss

The effect of various additives on the burning rate of AP and AP/carbon mixtures in PMMA tubes was measured at a constant pressure [871]. Potassium dichromate increased the burning rate better than chromium(III) oxide. A stoichiometric mixture of AP and iron powder had a very high burning rate. Another fuel tested was calcium stearate, which can also be used as a pelletizing aid.

The effects of additives on the rate of deflagration of AN and AP have been summarized in a book on the catalysis of explosive combustion by Glazkova [872].

A summary of the publications on the effects of catalysts on the burning rate of the self-deflagration of AP (in the absence of combustible fuels) is provided in Table 21.

Because there are so many publications on this subject, it was difficult to get the references fully organized. Due to a lack of other sorting criteria, we have arranged the literature here chronologically by the decade in which it was published.

The burning rate of copper-chromite doped AP can be enhanced by mixing in small amounts of charcoal, both as a fuel and as an opacifier. In trying to derive a correlation between theory and experimental results, a relationship between energy flux density I and exposure time τ was derived, which defines the boundary conditions necessary to cause initiation [204, 205]. A theory based on partial differential equations describes the space-time temperature distribution in the pellet in terms

Table 21: Burning rate increasing catalysts for AP.

Compound Name	Formula	References
Potassium permanganate	KMnO ₄	[873]
Iron(III) oxide	Fe ₂ O ₃	[873]

Ammonium dichromate	(NH ₄) ₂ Cr ₂ O ₇	[876]

of chemical reaction rates, heat of reaction, thermal conductivity, heat capacity, optical absorptivity, and surface reflectivity. Integration of the equation using the experimentally determined chemical and physical parameters and boundary conditions provided the temperature of the pellet and the temperature of the pellet surface as a function of time with flux as a parameter. From this solution, one was able to obtain the following two parameters for a given flux density (I). **(1)** The temperature $T(0, \tau)$ of the initiating surface at the moment τ_i of cut-off of the energy pulse. **(2)** A lower boundary for the minimum thermal ignition time.

Potassium dichromate is a very effective burning rate catalyst for AP [871]. Chromium(III) oxide is less effective and accelerates burning rates only up to 50.5 MPa (500 atm). Mixtures of AP and iron powder burn very fast.

The burning rate of AP-based composite propellants was unaffected by the addition of potassium chlorate to the AP [262], but metal chelates and metal acetylacetonates increased the burning rate at chamber pressures below 6.88 MPa (68.1 atm = 1000 psi). The activity of metals decreased in the order $\text{Cu} > \text{Fe} > \text{Co} > \sim \text{Mn}$. The most effective catalysts were those based on transition metals having two stable oxidation states which can readily flip-flop by exchanging a single electron. The addition of 1% of tributylamine reduced the burning rate.

Vanadium(V) pentoxide accelerates the burning of AP and its mixtures with fuels and metals [877, 878].

A correlation of experimental results for the burning rates of AP was derived from three areas of propellant research: **(1)** low-temperature isothermal sublimation studies; **(2)** the measurement of linear regression rates using the hot-plate pyrolysis technique; and **(3)** the combustion of AP at low ambient pressures through either preheating the AP, the use of solid volatile fuel, the passing of gaseous fuels through a porous bed of AP, or the formation of a diffusion flame above the AP using a counterflow of

fuel gases [879]. Each of these experiments should yield information about the rate of sublimation of AP. At first glance, even if one allows for experimental errors in the various types of measurements, the agreement between the results from the different techniques was not very good. In particular, the activation energy for the rate-controlling step was in doubt, with values ranging all the way from 20 to 60 kcal/mol being suggested by various authors ("all over the ballpark"). It was shown that, when allowances were made for the pressure-dependence of the sublimation rate, an acceptable degree of correlation between all the sublimation data could be obtained and sublimation rates could be calculated from a simple kinetic theory formula with reasonable values of the evaporation coefficient.

Using 38-mm diameter pressed end burning grains, it was shown that the burning rate pressure exponent for pure AP was positive and constant between 8.26 and 20.64 MPa (1200 and 3000 psi) [264]. There is no evidence of a negative pressure exponent in this pressure region if the AP surface area to perimeter ratio is large enough. Isothermal kinetic studies had shown that diammonium hydrogen phosphate negatively catalyzes the low-temperature AP decomposition while chlorate is a positive catalyst for this decomposition. Despite causing significant changes in the rate of the LTDs, these materials have only a limited effect on the AP combustion rate. The phosphate may affect the rate of surface diffusion of HClO_4 , and thereby the bimolecular reaction of HClO_4 with gaseous products. The decomposition of AP containing 0.025% chlorate was approximately an order of magnitude faster than pure AP. The decomposition proceeds via six different reaction mechanisms. The phosphate and chlorate or their decomposition products do not appear to affect the dissociative evaporative rate of the AP residue which is left after the LTD. Additives such as diammonium hydrogen phosphate and potassium chlorate, which change the AP LTD by as much as an order of magnitude, have only a limited effect on the burning rate of pressed AP strands. Pressed AP strands containing a relatively high concentration of phosphate (0.64%) have a smaller change in their burning rate pressure exponent near 6.88 MPa (1000 psi) than strands of pure AP. It is very dangerous to mix ammonium salts with chlorates because ammonium chlorate is very unstable and may render the mixture more sensitive to accidental ignition.

The decomposition, pyrolysis, and deflagration of pure and isomorphously doped AP containing K^+ , $\text{Cr}_2\text{O}_7^{2-}$, and MnO_4^- ions were followed by visual observations of quenched surfaces, which involved taking high-speed movies of the burning surface [779].

Copper chromite, iron(III) oxide, copper(II) oxide, and potassium permanganate were used to study the effect of catalysts on the deflagration pressure limit and the burning rate of AP [873, 880–882]. Copper chromite, Fe_2O_3 , and CuO increased the lower pressure limit of deflagration when present at small concentrations but decreased it at large concentrations. Potassium permanganate, both mechanically mixed and co-crystallized with AP, had a similar effect on the lower pressure limit. However, at large concentrations of KMnO_4 , an upper-pressure limit was observed,

above which deflagration could not be maintained. The effect of these catalysts on the burning rate varied over a wide pressure range. It was further observed that the effect of catalysts depended strongly on the way they are dispersed as well as their overall concentration. Catalysts were much more effective at smaller particle sizes.

Quenching the deflagration of catalyzed AP grains and examining the surface in the vicinity of the catalyst particles with SEM was done in the hope of explaining the mechanism of catalysts and to invent more active ones [883]. The catalysts used were ultra-fine copper(II) oxide and iron(III) oxide. Catalysis of burning of AP and its mixtures with combustible substances was investigated using optical and SEM and the effects of catalyst dispersion on burning rates were studied [884]. Fe_2O_3 , CuO , and CuCr_2O_4 were used as catalysts in amounts of 1–2.5 mass-% [885].

CuO or Cu_2O added to AP at 2 or 8% and pressed into pellets failed to sustain deflagration at room temperature and 373 K (100 °C) [876]. It was suggested that CuO is a better catalyst for thermal decomposition and Cu_2O is a better catalyst for the deflagration burning of AP.

In some cases, literature abstracts do not identify the types of compounds that were added to AP in an effort to change its burning rate. One must assume that most of these elements were added in the form of their oxides or perchlorates. The effects of various catalyzing additives such as Cu, K, Bi, Li, Co, Ba, Zn, Cr, V, and Fe compounds on AP combustion were measured and compared to 0.05–10% of $\text{K}_2\text{Cr}_2\text{O}_7$ [886]. The coefficient of catalysis (K) is defined as the ratio of the catalyzed burning rate to the uncatalyzed burning rate. Various regimes of the AP combustion rate were considered as well as changes in the coefficient of catalysis and combustion rate dependence on the amount and type of catalyst. Two pressure zones could be identified: 5.05–15.15 MPa (50–150 atm) where a slight increase of catalytic efficiency (K) occurs along with an increase in the linear burning rate (U_0), and 30.3–101 MPa (300–1000 atm) within which range K decreases with an increase in U_0 .

The combustion of AP in mixtures containing 2 or 8% of additives (metal oxides, other perchlorates, other ammonium salts, opacifiers) was measured at pressures ranging from 0.688 to 10.32 MPa (100–1500 psi) and initial temperatures of 298 or 373 K (25 or 100 °C) [876]. Additives tested included Cu_2O , CuO , Fe_2O_3 , Cr_2O_3 , CuCrO_4 , $(\text{NH}_4)_2\text{CrO}_4$, and $(\text{NH}_4)_2\text{Cr}_2\text{O}_7$. The addition of TiO_2 , ZnO , NH_4Cl , NH_4F , $(\text{NH}_4)_2\text{SO}_4$, NH_4HF_2 , $(\text{NH}_4)_2\text{HPO}_4$, $\text{Cd}(\text{ClO}_4)_2$, $\text{Cu}(\text{ClO}_4)_2$, or CaC_2O_4 inhibited the burning. Two per-cent of Fe_2O_3 increased the deflagration rate and temperature sensitivity significantly over that of pure AP. Samples with 8% of Fe_2O_3 at room temperature led to lower burning rates, a raised lower pressure limit and a higher slope than for pure AP. Raising the initial temperature to 373 K (100 °C) brought the burning rate back up to that of pure AP.

The effects of additives on the rate of deflagration of AP have been summarized in a book by Glazkova [872]. A well-written summary comparing the occasionally contradictory observations and conclusions about the effectiveness of copper oxides

and other catalysts on the decomposition and burning rate of AP was provided by Singh [869].

The combustion of mixtures of AP with various inorganic compounds of the following types were studied: oxides of copper and chromium, oxides of other metals, other perchlorates, other ammonium salts, and darkening agents [887]. The additives were generally added at the 2 and 8 mass-% levels. The rate of regression was measured from high-speed photography in a windowed bomb. Deflagration rates of AP with a total of 32 different additives were tested at two different additive concentrations, two initial sample temperatures (room temperature and 373 K = 100 °C), and several pressures from 0.69 to 10.32 MPa (100 to 1500 psi). Additives tested included various metal oxides and chromates, other perchlorates [LiClO_4 , KClO_4 , $\text{Zn}(\text{ClO}_4)_2$, $\text{Cd}(\text{ClO}_4)_2$, $\text{Cu}(\text{ClO}_4)_2$], and other ammonium salts [$(\text{COONH}_4)_2$, $(\text{NH}_4)_3\text{PO}_4$, $(\text{NH}_4)_2\text{SO}_4$, NH_4HSO_4 , NH_4Cl , NH_4F]. Much of the work that has been reported in existing literature relates to AP-catalyst reactions. Unfortunately, much of it is of questionable relevance to the deflagration situation.

The apparatus used in this investigation consisted of a stainless-steel window bomb that was capable of being pressurized at 13.76 MPa (2000 psi) and heated to 423 K (150 °C). A high-speed motion-picture camera was also utilized. Burning rates were calculated from surface regression distances per 0.10-second time intervals from high-speed motion-picture films. When this procedure was used to determine the burn rates of pure AP (both single crystals and pellets), the data scatter was of the order of ± 0.02 in./s. A SEM was used to view the surfaces of samples quenched while burning at various pressures. The quenching was accomplished using rapid depressurization ($dp/dt > 10^5$ psi/s).

The burning rates of AP catalyzed using calcined Cr_2O_3 , CuO , or Fe_2O_3 and the dependence of the burning rate of AP on pressure were measured in one set of experiments [888]. The surface properties of Cr_2O_3 , CuO , and Fe_2O_3 catalysts were examined using XPS. Attempts to establish correlations between the catalytic activity and surface properties were made. An electron-transfer catalytic mechanism was postulated in the catalytic combustion of AP with Cr_2O_3 and CuO as catalysts.

The effects of metal oxides applied to the surface of AP crystals and introduced into the propellant in the form of colloidal suspensions on the burning rate and thermal decomposition of AP were investigated [889]. It was found that the possibility of changing the burning rate by means of applying small additive concentrations (up to 0.5%) of the catalyst on the oxidizer crystal surface is determined by the chemical nature, the content of the compounds deposited on the oxidizer surface, and the structure of the coating formed on the AP surface.

5.15.2 Effects of Inhibitors on the Burning Rate of AP

The inhibiting effect of ammonium salts, such as ammonium carbonate, oxalate, citrate, tartrate or fluoride, and a reducing agent, such as diphenylamine, on the burning

rate of AP or AP/AN mixtures was investigated [890]. It was theorized that the effect of easily dissociating ammonium salts would consist of shifting the equilibrium of the reaction to the left, while the effect of diphenylamine would be either a reduction or a binding of the acid formed in the dissociation, thus inhibiting the further oxidation of ammonia. This assumption was verified experimentally through the combustion of “ammamol 80/20” (instead of pure AN which does not burn in the bomb) or AP (with or without the additives mentioned above) added in the amount of 5%. The rate of combustion was measured at varying pressures up to 101 MPa (1000 atm) in a constant-pressure bomb.

The deceleration of chemical reactions in the deflagration of AN or AP and some of their mixtures was studied in a constant pressure bomb over the pressure range from 1 to 1000 atm [891]. The deflagration of AP and ammonite 80/20 was decelerated also by adding readily-decomposed salts of ammonia. Assumptions regarding the mechanism of deceleration of the combustion process were suggested, based on the assumption of the possible role of nitric oxides and of a dissociation reaction of AN and AP.

The effects of the addition of up to 5% of organic additives on AP combustion characteristics (lower pressure limit of stable combustion, combustion rate, coefficients of inhibition in the exponential equation of combustion, and its dependence on pressure) at pressures up to 68 MPa (100 atm) were investigated [261]. There are three possible ways to inhibit the AP combustion process [892].

The burning rate of AP composite propellants is decreased significantly by the addition of SrCO_3 without increasing the pressure exponent of the burning rate. Results of micro-thermocouple measurements indicated that the burning surface temperature increased from 700 to 970 K due to the addition of SrCO_3 , although the heat-release rate in the gas phase remained unchanged [893]. DTA and TGA revealed that the AP decomposition temperature increased from 590 K to 620 K by adding SrCO_3 . The results of the analysis revealed that the reduction of the burning rate is caused by the increased AP decomposition temperature.

5.15.3 Effects of Contaminants on the Burning Rate of AP

Small traces of contaminants can have a noticeable effect on the rate of deflagration of pressed polycrystalline AP or AP single crystals. Pure AP doped with 0.05% K^+ produces burning rates very similar to those reported by others who have used AP of dubious purity [810].

Excess perchloric acid accelerates decomposition and the linear burning rate of AP while excess free ammonia retards it. Bircumshaw and Newman [348, 349] have suggested that the formation of centers of decomposition on the AP crystal surface may be associated with the formation of adsorbed perchloric acid. The induction period can be shortened by crystallizing an AP sample with 2% excess perchloric acid. Conversely, the induction period can be lengthened by passing some ammonia over the salt.

5.15.4 Effect of Chlorates on the Strand Burning Rate of AP

Chlorate ions are a potential contaminant in AP and are either carried over during the production or may form due to an interaction with a reducing agent in contact with AP with which AP is not compatible. Chlorates may form during radiolysis of AP. Investigations have been made on the effect of chlorate on the burning rate of AP. The burning of pure ammonium chlorate has been studied as well, although nobody would want to use it as a rocket propellant; its inadvertent formation must be avoided for sure. All pyrotechnic formulators have been warned against mixing ammonium salts with chlorates because ammonium chlorate may form during storage, which is very unstable and may render the mixture more sensitive to accidental ignition.

The thermal decomposition of AP containing 0.025% chlorate was approximately an order of magnitude faster than that of pure AP [264].

ClO_3^- ion is a catalyst for the decomposition of AP. It was found that impurities of ClO_3^- ions are typically present in even the purest commercial samples of AP [760].

Ammonium chlorate in the form of samples pressed into acrylic tubes of 4 mm diameter is capable of sustained combustion at atmospheric pressure [627]. Sample diameter influences the burning rate due to heat losses. Strand burning rates of ammonium chlorate are presented in Figure 40 in comparison to those of AP.

Figure 40: Comparison of combustion behaviors of ammonium chlorate and perchlorate. (Reproduced and modified from [627]; Cent. Eur. J. Energ. Mater.; licensed under Creative Commons <https://creativecommons.org/licenses/by-nc-nd/4.0/>).

In the pressure interval 0.4–40 MPa, the burning rate of NH_4ClO_3 can be described as

$$r_b = 12.96p^{0.6}$$

where r_b is the burning rate in mm/s and p is the pressure in MPa. For comparison, the burning rates of AP are also shown in Figure 41. As can be seen from the figure, ammonium chlorate burns much faster than AP in spite of having a lower burning surface temperature. The autoignition temperature of NH_4ClO_3 is much less than that of AP; it was reported as 393 K (130 °C) or even as low as 343–373 K (70–100 °C) compared to 623 K (350 °C) for AP. For the decomposition of some ammonium salts, a gas-phase model had been proposed. However, a calculation of the heat balance in the decompo-

Figure 41: Comparison of kinetic parameters of the combustion leading reaction (1 and 3) with decomposition kinetics in liquid states (2 and 4) for ammonium chlorate and perchlorate. (Reproduced and modified from [627]; Cent. Eur. J. Energ. Mater.; licensed under Creative Commons <https://creativecommons.org/licenses/by-nc-nd/4.0/>).

sition zone revealed that the heat available is insufficient to transform all salt into the vapor phase. Therefore, a significant part (at least 30%) of the decomposition reaction must take place in the condensed phase. The temperature sensitivity of the burning rate is much better represented by a condensed phase model rather than by a gas-phase model. Kinetic data of the rate-determining reaction of AP combustion and the kinetic data of AP decomposition in a liquid state are presented in Figure 41 in comparison to such data for NH_4ClO_3 .

A comparison of the constants reveals that the decomposition rate of NH_4ClO_3 is almost three orders of magnitude higher than that of AP combustion. This is the reason that ammonium chlorate burns much faster than AP.

5.15.5 Effects of Metal Perchlorates on the Strand Burning Rate of AP

At low concentrations, $\leq 30\%$ KClO_4 , the burning rate of the compressed AP/potassium perchlorate pellets increases with KClO_4 content. However, above 40% KClO_4 , it is difficult to maintain combustion [894]. The results can be explained in terms of the melt layer thickness, flame temperature, the resultant surface temperature, and the heat-wave penetration into the solid. A melt layer on the burning surface influences the deflagration behavior of the AP/potassium perchlorate pellets.

5.15.6 Effects of Non-Metal Perchlorates on the Strand Burning Rate of AP

Other perchlorates that have been added to AP in an effort to alter its burning rate and thermal stability include hydrazinium(1+) perchlorate, hydrazinium(2+) perchlorate, hydroxylammonium(1+) perchlorate, and nitronium (nitryl) perchlorate.

AP with an increased burning rate can be produced via “doping”, i.e., incorporating accelerators into the crystal structure. Unfortunately, the process also increases shock sensitivity. Thus, 100 g of AP and 0.0125 g of nitronium perchlorate were dissolved in 100% fuming HNO_3 at $<353\text{ K}$ ($<80^\circ\text{C}$). The solution was then cooled and the precipitate vacuum dried and pulverized [895]. Burning rate straws (5 cm long by 4 mm diam.) were packed with the material and burned. The average burning rates at 3.44, 6.88, and 10.32 MPa (500, 1000, and 1500 psia) were 27, 41, and 56 cm/s (10.74, 16.18, and 22.16 in./s), respectively. The burning rate of undoped AP at 6.88 MPa (1000 psia) was 34.8 cm/s (13.70 in./s) and calculated rates at 3.44 and 10.32 MPa (500 and 1500 psia) were 22 and 45 cm/s (8.74 and 17.85 in./s), respectively. A ~12% burning rate increase was achieved over that of undoped AP.

Compressed pellets made of mixtures of AP and trimethylammonium perchlorate burning at ambient pressure revealed an increase in the linear burning rate with increasing trimethylammonium perchlorate content, topping out at a maximum for a mixture containing 80 mass-% trimethylammonium perchlorate [896]. Isothermal thermogravimetry and DTA measurements indicated the possibility of eutectic melt formation.

5.15.7 Effects of Other Ammonium Salts on the Strand Burning Rate of AP

The addition of ammonium picrate in different concentrations to AP caused a slight increase in the burning rate of propellants prepared with this doped AP [897]. The thermal stability of doped AP was adversely affected but there was no systematic variation of the loss of stability with the dopant concentration.

5.15.8 Effects of Organic Compounds on the Strand Burning Rate of AP

The reactions of AP with organic compounds and the thermal stabilities of such mixes have already been discussed in Section 4.1.2.3. Strand burning rates of actual propellant formulations containing AP will be summarized in future volumes on solid propellants. Quite often, non-polymeric organic compounds have been mixed with AP as simulants for polymeric binders, which are easier to process than the sticky and messy prepolymers of real binders. In particular, investigators used fusible and volatile solid fuels that sublimed readily and allowed burning in the gas phase instead of pyrolyzing like polymeric binders. Such mixtures are not really useful as rocket propellants. They were mixed and burned just to satisfy academic curiosity. Because these organic compounds have no binder qualities, the ingredients are usually dry-mixed and then pressed into pellets for combustion studies. Some of the organic compounds were evaluated as stabilizers and as coolants for AP-based propellants.

Fuels tested for that purpose include paraformaldehyde [812, 814, 854, 855, 898, 899], hexamethylenetetramine [854, 855], and naphthalene [815].

The strand burning rates of mixtures of AP and organic fuels of the various chemical structures were measured by pressing $8 \times 4 \times 3.5$ mm pellets at $1000 \text{ kg}_f/\text{cm}^2$ and burning them in a constant pressure combustion bomb at pressures of 3, 20, and 40 atm [900]. High burning rates were observed with paraffin, stearic acid, palmitic acid, *o*-toluidine, and diaminodimethylmethane. It has been suggested that the burning rate of the mixtures depends on the calorific value of fuels of similar structures. Or, if the calorific value is the same, the burning rate of the mixtures depends on the strength of the chemical bonds and the structure of the molecules.

At low pressures, potassium perchlorate-based mixtures burn at higher rates than AP-based mixtures. Combustible substances were selected which do not contain carbon in their molecule and which yield ammonia (ammonium chloride) as the primary decomposition product. Other compounds with small carbon content (e.g., ammonium oxalate) were selected because they form ammonia upon decomposition. Urea was selected because it does not form ammonia during decomposition [826]. Also, hydrocarbons (naphthalene, paraffin) and other organic compounds were mixed with AP (with and without a catalyst), *o*-phenylenediamine and, finally, pure carbon-carbon black. Stoichiometric mixtures with particle dimensions of $\sim 250 \mu\text{m}$ were prepared and burned, then compared to mixtures with catalytic agents added in amounts of 5%. The lower combustion limits with respect to pressure and the dependence of

combustion rate on the pressure in the range up to 101 MPa (1000 atm) were determined.

The deflagration of AP and its mixtures with dicarboxylic acids (oxalic acid, malonic acid, phthalic acid) was evaluated experimentally. Attempts were made to develop a computer model based on partial differentiation of a basic thermodynamic equation that predicts the LPDL of AP and its mixtures [901]. For AP without the addition of dicarboxylic acid, the limit was at 2.02 MPa (20 atm). In the presence of dicarboxylic acid additives, a new subcritical regime below the conventional lower pressure limit was discovered in which AP does not burn. One of the parameters in the model is the melt layer thickness (see [902]).

5.15.9 Effect of Metal-Organic Compounds on the Strand Burning Rate of AP

The advantage of metalorganic compounds as burning rate additives is that they are miscible with the binders and can be placed at the surface of AP grains where they are needed the most. The disadvantage of metalorganic burning rate catalysts like ferrocene or metal acetylacetonates is that they are volatile and tend to migrate during aging of the propellant. It is thus of interest to study not only the effect of acetylacetonates (β -diketonates) on the burning rate of formulated propellants but also their effect on the strand burning of AP by itself.

The effect of various metal complex catalysts of 1,4,8,11-tetraaza[14]annulenes on the thermal decomposition of AN, AP, and a solid propellant containing AP as the oxidizer was studied using DTA and burning rate measurements [667]. For the solid propellants, which contained iron or vanadium complexes as catalysts, the burning rate increased by 1.6 times and their pressure index decreased to 80% compared to the burning experiments without a catalyst at a pressure of 5.0 MPa.

5.15.10 Effects of Other Additives on the Strand Burning Rate of AP

The mass burning rate versus pressure curve for unconfined pure AP has a region where the combustion starts pulsating and becomes unstable. Strangely, in the range 16.15 to 25.25 MPa (160–250 atm), the burning rate falls with pressure, while in the range of 25.25 to 50.5 MPa (250–500 atm) it remains constant. Only above 50.5 MPa (500 atm) does it increase with pressure [864]. Trying to explain this unusual behavior of AP by measuring the temperature distribution in the flame front with fine thermocouples revealed another anomaly: The heat release and the surface temperature were diminished even in the range between 4.04 to 15.15 MPa (40–150 atm) where the burning rate increased with pressure. It was suspected that water condensation may be the culprit. The addition of 1 mass-% of silica, silicone oil, or calcium stearate increased the burning rate and widened the range of stable combustion but calcium oxide prevented ignition in the range of 14.1 to 50.5 MPa (140 to 500 atm). The addition of 5% of SiO_2 stabilized the combustion of AP in PMMA tubes over the entire pressure range

up to 101 MPa (1000 atm). But the addition of 5% of ammonium oxalate reduced the burning rate of AP.

The burning rates of AP single crystals doped with K^+ and three concentrations of MnO_4^- exhibited one consistent feature in that the burning rates for the doped crystals were always below the pure AP rate over the pressure range tested [364]. In addition to this, the K^+ -doped AP had a pressure exponent of approximately 1.0 as compared to approximately 0.77 for pure AP. The highest (0.04% MnO_4^-) concentration doped AP, which would undergo self-deflagration, displayed a much lower burning rate. Therefore, it is presumed that increasing the MnO_4^- concentration results in lowering the single-crystal deflagration rate.

The deflagration behavior of pure AP in single-crystal and pressed-pellet form, and single crystals with controlled isomorphous substitution of K^+ , MnO_4^- , and $Cr_2O_7^{2-}$ ions were studied over the pressure range 2.06 to 41.3 MPa (300 to 6000 psia) using cinephotomicrography of burning samples and SEM of quenched samples [903]. The same additives can also be incorporated in micron-size whisker-shaped crystals of AP which are doped with co-crystallized burning rate catalysts [29].

5.15.11 Effects of Crystal Defects on the Strand Burning Rate of AP

A systematic study was undertaken on the combustion and thermal decomposition of AP pellets to investigate the effects of pelletizing pressure and the dwell time on the combustion and thermal decomposition of pelletized AP [904]. At constant pressure, increasing the dwell time resulted in an increase in the burning rate up to a maximum and thereafter decreased it. The dwell time required for the pellets to have a maximum burning rate was a function of pressure. The maximum burning rate was the same for all the pressures used. It was also unaffected by increasing the initial particle size of AP used to the range of 90 to 250 μm . In order to explain the occurrence of a maximum burning rate, pellets were examined for their thermal sensitivities, physical appearance, and the changes that occurred during pelletization with dwell time and pressure.

5.16 The Surface Temperature of Ammonium Perchlorate Combustion

Several experimenters have measured the surface temperature of deflagrating AP single crystals or pressed pellets, with or without additives, as part of other ongoing studies (mostly burning rate studies). Deriving the dependence of the surface temperature on pressure for AP is difficult. Finding the surface temperature is complicated due to not only a very steep temperature rise in profiles to a maximum value but also due to high-temperature oscillations in the zone near the surface. It is also rather difficult to establish whether AP melts at the burning surface. The presence of the liquid phase has been observed in several studies using microphotography of quenched samples

but it was not well-defined whether the liquid layer was produced during melting of AP or if it was a solution of decomposition products in AP. The AP surface temperature depends on the operating pressure. It increases from 880 to 1070 K as pressure increases from the lower pressure limit (~ 2 MPa) to 6 MPa [203].

The burning surface temperature of AP and AP/fuel mixtures has been measured using an IR optical method [814]. At atmospheric pressure, the temperature remained constant at 723 ± 30 K (450 ± 30 °C), irrespective of the rate of burning of the perchlorate-fuel mixture or the nature of the fuel. The disintegration process at the surface is most likely sublimation rather than kinetic decomposition controlled by a surface temperature. The rate of sublimation is thought to be controlled by the temperature gradient at the surface, which in turn is maintained by the gaseous ammonia-perchloric acid flame surrounding each particle. The temperature of this decomposition flame will increase if fuels are added.

The relation between the burning rate and the surface temperature of AP must be investigated to elucidate the combustion mechanism of composite propellants. The burning rate parameters that typically vary are the chamber pressure and the AP particle size. Optical or IR emission techniques can be used to measure surface temperatures but problems are posed by gas-phase emission, transparency of the AP, and the subsurface temperature gradient. A two-wavelength type of analysis of the surface-emission was proposed to overcome the subsurface-temperature-gradient problem [905].

In addition to thermocouple readings, measurements of the surface temperature of pressed strands of AP (done by recording the radiation from the surface at specific IR wavelengths) provided additional clues about the burning mechanism [898, 906]. Since they wanted to get AP to burn at lower (subatmospheric) pressures, the AP contained just enough of a volatile fuel (paraformaldehyde) to keep it going. IR measurements of the burning surface temperatures of oxidizer-rich AP/paraformaldehyde mixtures were made from sub-atmospheric pressures up to pressures of 2064 kPa (300 psia). Temperature determinations up to 413 kPa (60 psia) were reasonably reproducible, the values being compatible with the existence at the surface of an equilibrium between solid AP and the gaseous decomposition products, NH_3 and HClO_4 . Results above 413 kPa (60 psia) were rather erratic. The temperature gradients within the solid became too steep even for this method, which can penetrate as little as $2 \mu\text{m}$ of surface depth (see [899, 907]).

Calculations based on heat conduction and energy release indicate that the surface temperature remains constant over a wide range of pressures and the melt layer is at about 833 K (560 °C) [802, 803]. Other thermocouple measurements produced very low surface temperatures of 683 K (410 °C) at 5.05 MPa (50 atm) and 593 K (320 °C) at 10.1 MPa (100 atm). Thermocouple measurements may be inaccurate due to the catalytic action of the thermocouple metals if the wires are not shielded by an inert material.

The surface temperature of burning AP can be enhanced using laser illumination. The burning rate can thus be modulated by turning the laser on and off. The radiant flux-induced deflagration of AP at 1 atm has been investigated [908]. A 6-kW CO₂ laser was used as the radiant energy source and a force transducer was used to measure both steady and unsteady burning rates. The steady data were analyzed using the equivalence principle to obtain the burning rate-initial temperature sensitivity parameters k^* and σ_p^* . The dependence of σ_p^* on mean flux was also obtained from the equivalence principle and showed a decreasing trend with increasing flux (Figure 42).

Figure 42: Burning rate of AP as a function of laser radiant flux. (Reproduced and modified from [908].)

These findings have implications for steady-state burning rate predictions in motors with appreciable thermal radiant flux levels. These results are also useful for comparison with predictions of detailed models of the chemical kinetics and micro-structural combustion behavior of AP, both as a monopropellant and as an ingredient in composite propellants. In addition, the applicability of the one-dimensional momentum balance for obtaining the burning rate from recoil force was demonstrated.

Table 22 provides a summary of reported or calculated surface temperatures of burning AP. Most investigators reported that the surface temperature is not very dependent on operating pressure or burning rate.

As illustrated in Figure 41, experimental results obtained using thermocouple-aided measurements or burning surface pyrometry are scattered over a wide range. They can be grouped together along two lines that correspondingly describe the equilibrium gas pressure over the solid and melted AP surface [203].

Table 22: Summary of reported or calculated surface temperatures of burning AP.

5.17 Theoretical Treatment and Mathematical Models of Ammonium Perchlorate Combustion

AP by itself is not a useful rocket propellant. Nevertheless, mathematical models have been developed to interpret the burning mechanism of solid AP and to expand it to AP-based propellants with fuels. The establishment of a theoretical model requires the consideration of reactions in both the condensed (solid and molten) phase and in the gas phase and their interaction. Unfortunately, there is not sufficient information on the reactants in the AP condensed-phase reaction and the flame front to build an *a priori* model of its combustion. Various investigators have had to make different simplifying assumptions and that is where the inconsistency starts. Attempts have repeatedly been made to express the processes that take place during AP or other solid auto-decomposing compounds' combustion using a sequence of mathematical equations that will allow us to predict the burning rate as a function of input variables. So far, these efforts have only had limited success.

A small-perturbation investigation of AP deflagrations was made to determine the intrinsic stability of a one-dimensional burning configuration [910]. It was found that, above a certain pressure and dependent upon the numerical values used, a stable one-dimensional flame cannot exist. If the calculations are correct, for a preferred set of parameters, the pressure above which stability is impossible is between 4.26 MPa and 14.72 MPa (42.2 and 145.7 atm = 620 and 2140 psia), depending on whether the AP-gas interface is in equilibrium or is pyrolysis controlled. There are two reasons for the stability investigation in addition to the one given concerning its relevance to solid propellant combustion. First, there has never been a satisfactory theoretical explanation for the observed lower deflagration limit at roughly 2.064 MPa (20.43 atm = 300 psi). Secondly, it is known that deflagration ceases to be macroscopically steady and one-dimensional above about 13.76 MPa (2000 psi).

An attempt to derive a quantitative theory of the burning of AP used a rate law for the surface gasification. It examined the adjustable parameters and compared its predictions to earlier lower pressure limit measurements detailed by other investigators [911]. According to this model, the heat loss from the gaseous products was too small to account for the lower pressure limit (also called “lower deflagration limit”, which is abbreviated as P_{DL}). In order to compensate for this, it was assumed that the gas phase heat release per unit mass burned decreased with pressure. This accounted for the observed lower pressure limit but revealed other discrepancies. The disagreement in slope between the theoretical and experimental curves of burning rate versus pressure for pure AP may be in part due to an unknown experimental scaling factor on the radiant energy absorbed by the pellet. Experimentally, it was observed that:

- (1) P_{DL} was insensitive to sample size and to the substitution of helium for nitrogen as the ambient atmosphere;
- (2) P_{DL} increased as the particle size (sieve dimension) decreased; the particles are those of AP from which the pressed pellet is formed; and
- (3) Preheating the pellets lowered P_{DL} , and precooling the pellets raised P_{DL} .

Theories of the effect of catalysts on the burning rate of AP-based composite propellants differ in the interpretation of whether the effect of catalysts is stronger in the condensed phase or in the aerosolized gas phase. It was difficult to match the predictions of such theories with the experimentally determined burning rate data at varying catalyst levels and with different catalyst types. A model for the burning of AP was developed based on the following assumptions [563]:

1. An equilibrium pressure of $\text{HClO}_4 \cdot \text{NH}_3$ is established on the burning surface at the surface temperature for which the rates of Inami, Rosser, and Wise [128, 600] were used.
2. A surface exothermic reaction occurs in the condensed phase. The assumption that the decomposition reaction is a surface reaction is confirmed by experimental data, according to which the velocity of decomposition of AP is proportional to its specific surface.
3. The reaction in the gas phase is taken as a first-order reaction with respect to HClO_4 and zero-order with respect to NH_3 . Equality of the coefficients of diffusion and thermal diffusivity occurs.
4. Heat losses are disregarded.

One of the models that deals with competing evaporation processes and decomposition reactions in general terms (not just for AP) predicted a burning rate for AP at 6.88 MPa (1000 psia) of 1.2 mm/s. This is almost an order of magnitude below the actual measured data [912]. The divergence was explained by the formation of a liquid phase on the surface of the burning material.

An analytical model has been developed to describe the burning behavior of catalyzed AP for pressures below 10 MPa and used to explain the increase in both the

burning rate and the lower deflagration pressure limit (LDPL) of AP with catalyst content [913]. The peculiar increase of LDPL of AP by catalysts can be understood on the basis of inherent instability of the condensed phase deflagration wave decoupled from the gas phase deflagration wave. The effects of the addition of external heat, preheating, and the fuel added to AP on the LDPL were also explained using the model.

The deflagration of AP in the subcritical regime, below the LPDL (<2.03 MPa) designated as regime I', was modeled using a thermodynamic approach [902]. In this regime, deflagration was affected by augmenting the initial temperature (T_0) of the AP strand and by adding fuels like aliphatic dicarboxylic acids or polymers like CTPB. From this thermodynamic model, considering the dependence of burning rate (r) on pressure (P) and T_0 , the true condensed ($E_{a,c}$) and gas phase ($E_{a,g}$) activation energies, just below and above the surface respectively, were obtained. The data clearly distinguished the deflagration mechanisms in regime I' and regime I (2.03–6.08 MPa). A substantial reduction in the $E_{a,c}$ of regime I', compared to that of regime I, is attributed to the HClO_4 -catalyzed decomposition of AP. The excess heat transferred onto the surface from the gas phase is used to melt AP and hence $E_{a,c}$ in regime I, which corresponds to the melt AP decomposition. This was consistent with the similar variation observed for both the melt layer thickness and r as a function of P . Thermochemical calculations of the surface heat release supported the thermodynamic model and revealed that the AP sublimation reduced the required critical exothermicity of 1108.8 kJ/kg at the surface. It accounted for the AP not sustaining combustion in the subcritical regime I'. Further support for the model came from the temperature-time profiles of the combustion train of AP. The gas and condensed phase enthalpies, derived from the profile, was in excellent agreement with those computed thermochemically. The proposed thermodynamic model also satisfactorily explained certain unique features like intermittent, plateau, and flameless combustion in AP/polymeric fuel systems (see [901] also).

An AP deflagration model was proposed, which included combustion processes in the solid phase, liquid/gas mixed phase, and the gas phase, including detailed kinetic mechanisms [914]. It was assumed that AP decomposition proceeds via two parallel decomposition paths to form bubbles in which gas reactions can occur. The calculated results showed good agreement with experimental data in burning rate characteristics between 2.02 and 12.12 MPa (20–120 atm) and final equilibrium properties. The two mechanisms produced very different flame stand-off distances. The predicted temperature and species profiles were quite different also. To expand this model, a three-phase combustion model of the deflagration of AP was developed [915, 916].

A modified model was applied to compute the linear and non-linear combustion response properties of monopropellant AP burning [917, 918]. The kinetics constants were changed to achieve good agreement with response function data as well as with steady-state data. Supplemental mathematical analyses connected the AP model to the basic two parameters of the classical theory. It demonstrated the key factors which determine the nature of the combustion response.

In another model [919], a one-dimensional aero-thermo-chemical flow field was described through the solution of mass, energy, and species conservation equations. The unsteady one-dimensional phase heat transfer accounting for regression was solved in the condensed phase. The uncertain parameters for AP pyrolysis, gas-phase reaction, and extent of surface exothermicity were selected to ensure that the most certain of the measured parameters of AP combustion were correctly predicted. Parameters of interest are pressure index of stable combustion (an index of 0.77 between 2 and 7 MPa), the initial temperature sensitivity of the burn rate, σ_p (about 0.0021 to 0.0015 K⁻¹), range of surface temperatures (~850 to 875 K), and LPDL at 300 K (~2 MPa). The results obtained showed that the pressure index of AP combustion was 0.77 and σ_p was 0.0024–0.0023 K⁻¹. It was suggested that the LPDL is caused by a combination of loss of the liquid layer and transient conduction into the condensed phase and not by heat loss.

An interface model for AP deflagration flames included complex chemistry and detailed transport in the gas phase and heat conduction in the solid phase [920]. The interface condition considered sublimation of AP as well as reaction products obtained through a molten liquid phase. The resulting parameterized two-point boundary value problem was solved using a phase-space, pseudo-arclength, continuation method that employed Euler predictors, Newton-like iterations, and global adaptive gridding techniques. The use of boundary conditions for the temperature at the solid phase cold boundary led to a better understanding of reasons for extinguished flames such that it was possible to predict qualitative pressure extinction limits of AP flames subjected to heat losses. Preheated low-pressure flames, as well as high-pressure flames, were simulated in good agreement with experimental results.

To obtain rate constants of the dominant reaction on the combustion of AP, Sinditskii et al. used the Zeldovich condensed-phase model, data on AP burning rates in the pressure interval of stable combustion 2–6 MPa, surface temperatures derived from the generalized expression for gas pressure over the solid or melted AP surface, and took into account heats of phase change and melting, which are 88 and 251 J/g (21 and 60 cal/g), respectively [838]. The results are shown in Figure 43 in comparison with decomposition kinetics of gaseous perchloric acid, initial rates of decomposition of a liquid eutectic of AP with guanidine perchlorate, and low- and high-temperature AP decomposition in the condensed phase.

An excellent agreement was demonstrated between rate constants of the rate-determining reaction in combustion

$$k = 10^{11.8} \cdot \exp(-20210/T),$$

perchloric acid decomposition reaction, and AP initial decomposition in the liquid state. This was claimed to be convincing evidence for the previously stated assumption of the leading role of chemical processes in the thin liquid surface layer on the surface of burning AP (see [921] also).

Legend: Points (1) and dashed lines (2): perchloric acid decomposition in the gas phase; initial decomposition of liquid eutectic of AP and guanidine perchlorate (3); AP decomposition in the solid-state at low (4) and high temperatures (5).

More recently, and due to the improvement of computers and kinetic data, models based on global kinetics are being replaced by modeling of gaseous flames above burning propellants based on gas-phase detailed kinetics. Most of the models are essentially a modern development of the Beliaev-Zeldovich gas-phase model. Due to different activation energies, the decomposition reaction is the rate-limiting stage at low temperatures, and secondary redox reactions are the limiting ones in the high-temperature regime. In most cases, the heat release in the condensed phase is controlled by decomposition kinetics. Knowledge of detailed chemistry is needed only for the modeling gas phase. Thermocouple-aided experimental studies on the combustion of different energetic materials have found that the surface temperature is equal to boiling point or, in the case of salts, dissociation temperature [838, 839]. One can suppose, therefore, that there exists a microscopic (not a macroscopic) equilibrium at the surface between boiling substances. Energetic materials can be heated in the condensed phase to their maximum temperature, which is the boiling point, or in the case of onium salts, their dissociation temperature. It is very interesting to compare

the surface temperature of decomposing ammonium salts to the acid strength of the parent acid, which relates to the dissociation equilibrium constant for the dissociating salt (Figure 44).

Figure 44: Comparison of surface temperatures of burning onium salts and strength of acids. (Reproduced and modified from [203].)

5.18 Combustion of Ammonium Perchlorate in Solid Propellants

There are too many publications on the combustion of AP in rocket propellants and we cannot reference them all in this book. The main application aspects of such papers will be discussed in future volumes on solid propellants, mostly concerned with formulating and processing composite propellants. Here we have assembled some related papers where the emphasis is on the kinetics of AP decomposition as an oxygen source and the effects of AP particle size and additives on the burning rates of such propellants. In many cases, the studies were conducted side-by-side using AP, with and without combustible fuels (binders or simulated binders). Therefore, there is some overlap and some unavoidable repetition between this chapter and some of the preceding chapters.

Because there are so many publications on this subject, it was difficult to get the references organized in a systematic way. Due to a lack of other sorting criteria, we

have arranged the literature here chronologically by the decade in which it was published.

The results of surface temperature measurements on AP burning under a variety of conditions from 5.5 to 2064 kPa (0.05 to 20.43 atm = 0.8 to 300 psia) point to the possibility that some heat release is likely to occur within the solid surface although the combustion in all pressure regions appears to be dominated by gas-phase reactions [922]. Results with catalysts that are supposed to increase the extent of the condensed phase reaction do not alter this conclusion.

Experimental evidence of the gasification process of AP burning under a very wide variety of conditions showed that AP dissociation is generally better represented by a kinetic decomposition law than by an equilibrium law [858]. A kinetic decomposition law would predict an activation energy of 125 kJ/mol (30 kcal/mol). During combustion, some exothermic redox reactions in the condensed phase accompany the dissociation of the salt. At low pressures, the burning rates of composite mixtures of AP with organic fuels were little affected by fuel-binder properties (other than by the heat of combustion), however, at high pressures the opposite was true. Possible explanations for this have been proposed. At constant final-flame temperature, the volumetric oxidizer loading of a binder appears to be more important than its thermal stability, and the idea of a fuel “barrier” hindering propagation of the AP monopropellant flame at high pressures is supported. Rates of flame travel along AP/binder interfaces in sandwiches are not very different from the burning rates of the corresponding composite propellant. This does not seem to be a rate-controlling process.

If propellants are prepared from AP, which has been preheated until the low-temperature reaction was complete, the burning rate was not different from that of controls that had not been preheated [879]. It was theorized that any thermal decomposition occurring in the solid phase ahead of the combustion zone has no significant effect on the burning rate (see [15, 923, 924] also).

The burning rates of fine, coarse, and bimodal particle size mixtures of AP with PS and poly(methylmethacrylate) were investigated [925]. Fe_2O_3 with a specific surface of $5.3 \text{ m}^2/\text{g}$ was used in an amount of 1% as a catalyst. In the finely dispersed systems, the efficiency of the catalyst was lowest in mixtures with the maximum burning rate. In coarsely dispersed mixtures the efficiency decreased with increasing content of combustible material. In mixtures containing a bimodal oxidizer particle size distribution, the efficiency changed with the ratio between the fine and coarse fractions of oxidizer and the change was not linear. An attempt was made to explain the dependence of the efficiency of the catalyst on the degree of dispersion of the ingredients based on the general theory of combustion of mixtures.

An evaluation of the decomposition kinetics of energetic materials (including AP) in the combustion front of solid propellants was based on experimental data and theoretical calculations (see [838, 921] also). This paper is an excellent summary of the relationship between decomposition kinetics and burning rates, supported by a long literature reference list containing 96 references of prior publications.

6 Compatibility With Ammonium Perchlorate

AP comes into contact with many different materials during its manufacture, transport, storage, grinding, sifting, and final processing stages (with binders into propellants and casting into a motor casing). Formulated propellants then are put in contact with ignitors, inhibitors, liners, and moisture barriers while they are stored in the field under a variety of conditions. Although AP is a solid, and solid-solid reactions are much slower than reactions with liquid rocket propellants, the compatibility of AP with various materials must be known in order to avoid problems.

6.1 Compatibility of Ammonium Perchlorate With Metals

The compatibility of AP with metals is very dependent on the moisture content of the material. Moist conditions will accelerate corrosion.

6.2 Compatibility of Ammonium Perchlorate With Polymers

Essentially all AP eventually comes into contact with polymers when it is processed into composite solid propellants with polymeric binders. The volume on solid propellants contains several chapters on solid propellants with AP and diversity of binders. AP is compatible with most, but not all of them. Protective coatings were necessary in some instances.

6.3 Compatibility of Ammonium Perchlorate With Wetting Agents

Sometimes AP is coated with wetting agents to improve the bond between the inorganic and organic phases in a heterogeneous mix. AP must be compatible with binders, curing agents, and wetting agents.

A dendritic bonding agent that can coat AP was characterized using SEM, XPS, and micro-infrared [926]. This coating forms a viscous film on the surface of AP; the coverage can be up to 47% based on XPS analysis. The coverage can be improved by increasing the CN group content. Micro-IR analysis indicated that H-bonds are formed between the wetting agent and N—H groups.

6.4 Compatibility of Ammonium Perchlorate With Plasticizers

Several of the plasticizers used in composite modified double-base (CMDB) propellants are nitrate esters that may react with AP and degrade with time [927].

6.5 Compatibility of Ammonium Perchlorate With Pyrotechnics

Most pyrotechnic formulations contain potassium perchlorate, which is compatible with AP. Pyrotechnics of various compositions may be in contact with AP where igniters are installed in the immediate vicinity of AP-based solid propellant grains. Contact with pyrotechnics that contain chlorates must be avoided.

7 Toxicity of Ammonium Perchlorate

Prior to the development of AP as a rocket propellant, potassium perchlorate had been used as a medicine at various times during the last 60 years to treat hyperthyroidism. Since World War II, AP has been used as a propellant for rockets, resulting in increased production and, unfortunately, dispersion of perchlorates in the environment. In 1997, the assay sensitivity for perchlorate in water was improved by two orders of magnitude from 0.4 mg/L (ppm) to 4 µg/L (ppb). As a result, public water supplies in Southern California were found to contain perchlorate ion concentrations in the range of 5 to 8 ppb, and those in Southern Nevada were found to contain 5 to 24 ppb. Research programs have been developed to assess the safety or risk from these exposures and to assist state and regulatory agencies in setting a reasonable safe level for perchlorates in drinking water.

The extent of perchlorate contamination of water sources nationwide was not discovered until 1997. As of 2005, over 11 million people had perchlorate in their public drinking-water supplies at concentrations of 4 ppb (4 µg/L) or higher. The reasons for the increased interest and awareness of the potential accidental exposure to perchlorates from drinking water are the development of ever more sensitive methods of analysis (sensitive to below ppb levels) and the concern about adverse effects in sensitive populations (fetuses, babies, elderly). However, there has been a great amount of uncertainty and controversy about the suspected and purported effects of perchlorates on human health and the environment [928]. In response to the concern of the public, the DoD in the US and other government agencies initiated a series of programs with the following three objectives: **(1)** development and testing for effective remedial technologies for clean-up in drinking water, soils, and groundwater, **(2)** improved methods to characterize perchlorate-contaminated sites, and **(3)** improved understanding of the human and ecological health effects of perchlorate exposure.

There are several summaries of perchlorate toxicity, environmental effects, and occupational health implications, particularly following the discovery of widespread pollution of aquifers and drinking water which became apparent in the 1990s [929–931]. Even the legal and liability aspects of perchlorate pollution are now dealt with in a book [932].

The *Toxicological Profile for Perchlorates* report was published by the US Department of Health and Human Services, the Public Health Service, and the Agency for

Toxic Substances and Disease Registry [933]. It is a very comprehensive summary that includes chapters on Public Health (Chapter 1), Relevance to Public Health (Chapter 2), Health Effects (Chapter 3, which occupies almost half of the volume of the entire study), Chemical and Physical Properties (Chapter 4, which is very short), Production, Import/Export, Use and Disposal (Chapter 5), Potential for Human Exposure (Chapter 6), and Analytical Methods (Chapter 7). This report also contains data on perchlorates other than AP, including magnesium, potassium, sodium, and lithium perchlorate. It provides a very good introduction to the potential problems with widely dispersed perchlorate contamination in the vicinity of inhabited areas and drinking or irrigation water sources.

The chemical and rocket propellant industry have combined forces to provide up-to-date information on the perchlorate situation in the US. The Perchlorate Information Bureau (<http://www.perchlorateinformationbureau.org>, formerly the Council on Water Quality) is supported by Aerojet, AMPAC, and Lockheed Martin. These companies have worked co-operatively with the EPA to increase scientific and medical understanding of perchlorate risk to human health. The aforementioned website will help get the true facts out about perchlorates, based on more than five decades of peer-reviewed scientific research and study, and will ensure that it has its rightful place in public discussion. According to credible data and research available, perchlorates do not cause cancer in humans or birth defects and it is not stored within the body.

Since the 1950s, potassium perchlorate has been used in the US and abroad to treat thyroid disorders in human patients. As a result, a wealth of information exists about perchlorate toxic effects and how it relates to human health. The doses used for medical treatment are tens of thousands of times greater than the low levels of perchlorate detected in drinking water.

During the past two decades, millions of dollars have been spent studying the possible health risks of perchlorate because of its presence at trace levels in some water supplies. Scientific and medical research shows that the low levels of perchlorate being detected in drinking water are not dangerous to human health. These studies on adults, newborns, and children provide a reason to believe that low levels of perchlorate (even at levels many times higher than the minute amounts being found in some drinking water supplies) have no measurable effect on pregnant women or fetuses. Scientific evidence (e.g., the National Academy of Sciences [NAS] report and other credible and peer-reviewed studies by respected and independent medical researchers) does not link low levels of perchlorate to thyroid problems or thyroid cancer in humans.

In February 2005, the EPA established its official reference dose (RfD) of perchlorate at $0.0007 \text{ mg kg}^{-1} \text{ d}^{-1}$ and translated that number to a Drinking Water Equivalent Level of 24.5 parts per billion. This level is consistent with the recommended RfD included in NAS' January 2005 report on the health implications of perchlorate [934].

Several of the toxicity studies referenced in this section have been conducted with potassium perchlorate or sodium perchlorate instead of AP. The type of cation present does not appear to have much of an influence on perchlorate toxicity.

In 2005, the Government Accountability Office (GAO) in the US issued a report on perchlorate monitoring and detection. They concluded that a system to track sampling and clean up results is needed [935].

In August 2010, the same Government Accountability Office issued a report on perchlorate occurrence and the regulatory actions taken to date [936]. It stated that occurrence is widespread but at varying levels and that federal agencies have taken some actions to respond to and lessen releases. GAO was asked to examine **(1)** what is known about the extent to which perchlorate occurs in the nation's water and food supply and its likely sources; **(2)** what actions DoD, NASA, and Department of Energy (DoE) have taken to respond to or lessen perchlorate releases; and **(3)** what actions states such as California and Massachusetts have taken to regulate perchlorate. To address these questions, GAO analyzed data from the EPA, DOD, NASA, and DOE, then reviewed agency documents, and interviewed federal and state officials, researchers, and others (see [937, 938]).

7.1 Acute Toxicity of Ammonium Perchlorate – Animal Studies

It is surprising that considering the huge quantities of AP consumed around the world, there are only a few very antiquated sources for the lethal dose 50% (LD_{50}) of AP in animal studies. Published toxicological studies on perchlorates have focused primarily on laboratory mammals such as rats and mice. This is partly due to the medical interest in perchlorate use as a drug to block iodine uptake and thus prevent hyperthyroidism (Graves' disease). Most toxicity evaluations of perchlorates focus on the levels of thyroid hormones triiodothyronine (T3) and thyroxine (T4) because it is generally assumed that deficiencies of these hormones affect growth and development as well as metabolism in animals.

7.1.1 Oral Toxicity of AP – Animal Studies

The oral LD_{50} of AP in white rats was reported to be 3556 mg/kg [939]. Looking at the title of this paper, one must ask, "How come the Russians already had concerns about perchlorates in drinking water reservoirs in 1963?" It is quite possible that they recognized the hazards of perchlorate releases into surface waters before the US did. In general, it appears that rabbits are more sensitive to the acute effects of perchlorate than other rodents.

The AMPAC Material Safety Data Sheets (MSDS) lists the following LD_{50} data, but the source of these data was not stated:

- Oral LD_{50} : rat; 4200 mg/kg
- Rat-par-LDLo = 3500 mg/kg
- Oral LD_{50} : rabbit; 1900 mg/kg
- Rabbit-par-LDLo = 750 mg/kg

Other sources state:

Toxicity:

- ORL-RAT LD₅₀ 4200 mg/kg
- SCU-RAT LD₅₀ 1600 mg/kg

Toxicity data

- ORL-RAT LD₅₀ 4200 mg/kg
- SCU-RAT LD₅₀ 1600 mg/kg
- ORL-RBT LD₅₀ 1900 mg/kg
- IPR-MUS LDLO 2000 mg/kg

Because perchlorate salts are completely dissociated in water and the associated cations (Na⁺, K⁺, NH₄⁺) are widely distributed in nature, many toxicological reviews assume that the contribution from the cations to overall toxicity is negligible and report the perchlorate ion concentration only, such as in Table 23.

Table 23: Summary of median lethal dose (LD₅₀) data for perchlorate salts.

Species	Route of administration	Chemical form	Perchlorate ion concentration ^a (mg/kg)
Rabbit	Oral	NH ₄ ClO ₄	635–1610
Mouse	i.p.	NaClO ₄	934
Mouse	Oral	NH ₄ ClO ₄	1610–1690
Guinea Pig	Oral	NH ₄ ClO ₄	2800
Rat	Oral	NH ₄ ClO ₄	2960–3560

i.p. = intraperitoneal

^aPerchlorate ion concentration is determined by multiplying the concentration of perchlorate salts by weight fraction perchlorate ion (NH₄ClO₄ = 0.847, NaClO₄ = 0.812, KClO₄ = 0.718).

Data source: [938], also reported in [940].

7.1.2 Pulmonary Toxicity of Perchlorates – Animal Studies

In addition to the thyroid gland, other potential target organs of perchlorate toxicity are the lungs and kidneys. Perchlorate toxicity can also impact blood.

In order to explore whether AP could cause pulmonary fibroblast proliferation, pulmonary fibroblasts of mice were cultured *in-vitro* [941, 942]. After three generations, cell cultures were treated with 50, 200, and 500 mg/L AP for 48 hours. The fibroblasts exposed to quartz (300 mg/L) were taken as the positive control and normal cultured fibroblasts as the negative control. Comparing morphological changes in the AP-treated groups with the negative control group, there was no significant difference in the shape of the cell slice, dimension, proportion between karyon and cytoplasm, the density of collagen, or cell thickness. However, in the positive control

group treated with quartz, there were a series of changes, such as cell enlargement, increase in cell quantity, enrichment in cytoplasm, and density of collagen. It was concluded that proliferation and collagen hyperplasia of fibroblast were not affected by AP *in-vitro*.

Similar results were obtained in rats. The levels of cell counts, tumor necrosis factor TNF α , MDA, hydroxyproline (HYP), and the synthesis of collagen in rat lungs after rats were injected with AP by intratracheal instillation were measured. It was found that AP could bring about acute lung damage and inflammatory reaction [943]. The levels of TNF α of different groups at different times were obviously higher than the normal control group ($P \sim 0.05$). AP adversely affected the levels of MDA, HYP, and the synthesis of collagen. But AP caused no obviously pathological change of pulmonary fibrosis.

In a similar experiment, rats were injected with AP by intratracheal instillation for seven to 29 days to allow a pathological examination of lung tissue [944]. This revealed that AP could bring about an acute inflammatory reaction but no obvious pulmonary fibrosis. There was no obvious change in the level of HYP in embryo pulmonary fibroblasts after administering AP. The level of TNF- α in the low dose group was higher than that of a negative control group ($P \sim 0.01$). The highest level was found after 29 days.

AP appears to be cytotoxic to alveolar macrophages [945]. In another experiment, alveolar macrophages were treated with AP for 24 hours [946]. Pulmonary fibroblasts were cultured with the supernatant of an alveolar macrophage medium. Rats were treated with AP by intratracheal instillation and euthanized after three days following which the TGF- $\beta 1$ mRNA content in the lung was examined. The positive staining macrophages in low and high AP groups and the quantity of TGF- $\beta 1$ in the high AP group were obviously higher than those in the control group ($P \sim 0.01$). However, there was no significant difference in the proliferative activity and the HYP content of pulmonary fibroblasts in all groups. The mRNA contents of TGF- $\beta 1$ in three AP groups were all significantly higher than that in the control group.

7.1.3 Hematotoxicity of Perchlorates – Animal Studies

In order to study the effect of AP on routine blood tests and serum biochemical indices in animals, 80 rats were randomly divided into four groups: one control group (physiological saline) and three AP treatment groups [947]. For the treatment groups, AP was administered once into the trachea of the rats at doses of 48, 96, and 192 mg/kg body weight, respectively. There was no significant difference among routine blood indices of various dosed groups following this AP treatment ($P \sim 0.05$). On the third day of treatment, the serum activities of alanine aminotransferase (ALT) for both middle and high dose AP groups (86.7, 85.5 U/L) were higher than that of the control group (56.6 U/L, $P \sim 0.05$). On the seventh day of the treatment, the contents of HYP of the AP low, middle, and high dose groups (17.4, 17.1, 18.2 $\mu\text{g/mL}$) were higher than that of

the control group (13.3 µg/mL, $P \sim 0.01$). On the 28th day of treatment, the content of urea nitrogen (19.4 mmol/L) was higher than that of the control group (14.7 mmol/L, $P \sim 0.05$). There were no toxic effects of AP found upon routine blood tests of rats. The ALT and HYP in the serum of rats increased significantly in the short term.

7.2 Metabolic Pathways of Ammonium Perchlorate

The bloodstream carries perchlorate to all parts of the body. Perchlorate is not changed or metabolized inside the body. A few internal organs (for example, the thyroid, breast tissue, and salivary glands) can take up relatively large amounts of perchlorate from the bloodstream. Perchlorate generally leaves these organs within a few hours. In the blood, perchlorate passes into the kidneys, which then release it into the urine. The body begins to clear itself of perchlorate through the kidneys within ten minutes of exposure. Perchlorate is excreted unchanged by the kidneys with a half-life of approximately six hours.

Perchlorate reached a maximum concentration (>3% of the administered dose/g tissue) in the thyroid gland of rats four hours after an intraperitoneal injection of radio-labeled potassium perchlorate ($K^{36}ClO_4$; 18 or 24 mg ClO_4 /kg) [948]. The elimination half-time for the thyroid was estimated to be approximately ten to 20 hours in rats.

A model for the metabolic pathways, consumption, and excretion of perchlorate in rats can eventually be extended to other mammals [949].

7.3 Thyroid Gland Interference by Ammonium Perchlorate

The majority of perchlorate salts are extremely soluble and mobile in natural water. As a result, they have become ubiquitous in surface, ground, and drinking water in several states of the US. The ingestion of perchlorate from contaminated water can interfere with the production of thyroid hormones because perchlorate competes with iodide uptake via the thyroid gland. It is especially dangerous for fetuses and neonates because thyroid hormones play a significant role in neurodevelopment. New analytical methods have been developed to detect perchlorates in water [950].

The main target organ for perchlorate toxicity in humans is the thyroid gland. Perchlorate anion affects the functioning of the thyroid and pituitary glands. Perchlorate has been shown to partially inhibit the thyroid's uptake of iodine (iodide) and is called a thyroid endocrine disruptor [951, 952]. Perchlorate and iodide compete for the same receptors. The competitive absorption of perchlorate and iodide is due to the similar energy of hydration and ion radii of the two ions [953]. Although not demonstrated in humans, it is anticipated that people exposed to excessive amounts of perchlorate for a long time may develop a decreased production of thyroid hormones. The medical name for this condition is *hypothyroidism*. Iodine is required as a building block for

the synthesis of thyroid hormone. Nowadays most table salts contain added iodide to assure an adequate supply of iodide in the diet even in the absence of a challenge by perchlorate. Populations living near seashores are less likely to develop iodine deficiency diseases because the ocean spray carries seawater (and iodide) aerosols inland. The thyroid gland produces two hormones, thyroxine (T4) and triiodothyronine (T3) from their precursor thyroglobulin, which circulate in the bloodstream and are primarily bound to protein. Thyroid hormone synthesis and secretion are normally maintained within narrow limits by an efficient regulatory mechanism. Specifically, decreases in serum thyroid hormone concentrations lead to increases in the secretion of thyrotropin (thyroid-stimulating hormone, TSH) by the pituitary gland, and increases in serum thyroid hormone concentrations lead to decreases in TSH secretion. TSH stimulates virtually every step of thyroid hormone production and secretion, and such tight control of TSH secretion maintains thyroid hormone production and secretion within normal or nearly normal limits. This thereby protects against both hypothyroidism (deficiency of thyroid hormone production) and hyperthyroidism (excess of thyroid hormone production). The pituitary gland produces and releases TSH, which is released when circulating levels of thyroxine and triiodothyronine decrease.

T4 is largely a precursor hormone with little or no intrinsic biologic activity. It is converted to T3, the biologically active thyroid hormone, in most tissues of the body. T3 is required for the normal development of the central nervous system in fetuses and infants. Its actions include stimulation of the development and growth of neurons (nerve cells) and glial (supporting) cells, the formation of synapses (connections) between neurons, the formation of the myelin sheaths that surround neuronal processes, and the development of neurotransmitters that transmit signals from one neuron to another.

Iodine is a component of T4 and T3, and the transfer of iodide from the circulation into the thyroid gland is an essential step in the synthesis of the two hormones. Iodide transport into the thyroid is mediated by a protein molecule known as the sodium (Na⁺)/iodide (I⁻) symporter (NIS). NIS molecules bind iodide with very high affinity but they also bind other ions that have a similar shape and electric charge such as perchlorates. Perchlorates can affect thyroid function because it is an ion that competitively inhibits the transport of iodide into the thyroid by the NIS.

Perchlorates have been used as a medicine to reduce hormone outputs in patients with hyperthyroidism, hyper-functional thyroid glands associated with Graves' disease, but its use has now been discontinued. These patients unwittingly served as "guinea pigs" and their medical history data were mined retroactively in an effort to establish the safe no-effect level of perchlorate in drinking water. Doses of perchlorate range from <1 mg kg⁻¹ d⁻¹ to >20 mg kg⁻¹ d⁻¹ with typical doses in the range of 6–14 mg kg⁻¹ d⁻¹. The effects observed include the blockage of iodine uptake and iodine discharge by the thyroid gland. Because of side effects and the development of better anti-thyroid drugs, the use of perchlorate to treat hyperthyroid patients largely ceased in the US by the late 1960s.

Children and developing fetuses and people with pre-existing thyroid disorders may be more susceptible to perchlorate than normal adults because thyroid hormones are essential for normal growth and development [954–957]. Two studies were conducted of newborn babies and school-age children from an area in Chile where levels of perchlorate in the drinking water were much higher than those detected in some US water supplies due to natural sources of perchlorate. No evidence of abnormal thyroid function was found among the babies or the children. The effects of perchlorate are neglectable as long as normal diets contain sufficient iodine (iodide). Perchlorate is accumulated in thyroid follicle cells and lumen where it competes with iodide [958].

7.3.1 Thyroid Gland – Animal Studies

The pituitary-thyroid system of rats is similar to that of humans. For example, decreases in thyroid hormone production result in increased secretion of TSH, which then increases thyroid production and releases T4 and T3. However, differences in binding proteins, binding affinities of the proteins for the hormones, turnover rates of the hormones, and thyroid stimulation by placental hormones lead to important quantitative differences between the two species. Therefore, although studies in rats provide useful qualitative information on the potential adverse effects of perchlorate exposure, they are limited in their utility for quantitatively assessing human health risks associated with perchlorate exposure.

Several animal studies have demonstrated the effect of perchlorates on the thyroid and its hormones.

Orally administered perchlorate failed to affect deciduoma formation or pregnancy but thyroid gland weights were significantly increased in Wistar rats exposed to 1% KClO_4 in the drinking water on days two through eight of gestation [959].

Thyroid weights of Wistar rat dams and their litters were significantly increased as the result of 2440 mg/kg KClO_4 in the drinking water during gestation [960]. The controls with potassium chloride suffered no such effects.

There is a lack of dose-response studies on the effect of perchlorate on the thyroid-pituitary gland system. Only a few studies have quantified the effect. Mannisto et al. [961] detected perturbations in the thyroxine and triiodothyronine and TSH levels in male Sprague-Dawley rats fed with 0 to 500 mg/L ClO_4^- in their drinking water for four days.

Suckling Wistar rats became acutely iodine deficient by dam exposure to 1.23 g/L NaClO_4 in the drinking water from birth through day ten after birth [962]. Pharmacokinetic modeling of the plasma, thyroid, and skin equilibrium demonstrated decreased iodide concentrations compared to controls, increased iodide uptake by the thyroid, and decreased skin iodide uptake. In a similar test using Sprague-Dawley rats that were fed with 0 to 250 mg ClO_4^- in drinking water for 14 days, the thyroglobulin and TSH levels increased but the triiodothyronine level decreased.

The thyroid follicle lumen sizes of thyroid glands of five-day and 90-day-old rat pups whose dams were exposed to AP were measured and morphometrically assessed to establish a RfD for AP. The dams were exposed to a daily oral intake of 0, 0.1, 1, 3, or 10 mg AP/kg body weight [963]. The post-natal evaluation spanned 81 days. The pups received further exposure to perchlorate through day ten of lactation. Tissue samples were stained and measured with a charge-coupled device (CCD) camera on a microscope and a digital image analysis system for follicle count and follicle lumen area. Female samples taken from five-day-old animals formed a smooth dose-response curve with decreasing follicular lumen sizes at each increasing dose level with a significant difference at the highest dose (10 mg/kg). Observations in five-day-old female rats gave a smooth dose-response curve but the data for five-day-old males at 1 mg/kg were not much different from the controls. The dose-response of the males was valid if the 1 mg/kg data points were omitted. Animals that were kept for 81 days post-exposure showed no significant differences between dosage groups and controls for either sex. Based on these data, the **no observable adverse effect level** (NOAEL) of $1 \text{ mg kg}^{-1} \text{ d}^{-1}$ was recommended. The **lowest observable adverse effect level** (LOAEL) was at $3 \text{ mg kg}^{-1} \text{ d}^{-1}$.

Significant gender differences in sensitivity to AP were observed when eight groups of 12 Sprague-Dawley rats, six male and six female, were exposed to incremental doses of AP in their drinking water [964]. The results indicated that triiodothyronine (T3) levels in male and female rats fell. However, thyroxine (T4) levels in male rats remained relatively unchanged. Reverse triiodothyronine (rT3), thyrotropin (TSH), and thyroglobulin (Tg) all increased in both males and females. These results confirmed that the AP anion blocked the uptake of iodine in the thyroid. Although an estimated threshold could not be determined, the NOAEL for AP on the TSH levels was 0.44 mg/kg/d for male rats and 0.124 mg/kg/d for female rats. These NOAELs were consistent with the assumptions made by the EPA, which estimated a NOAEL of 0.14 mg/kg/day for perchlorates.

In a 14-day drinking water pilot study in rats, the animals were exposed to one of seven doses of perchlorates ranging from 0.1 to $39.9 \text{ mg ClO}_4^- \text{ kg}^{-1} \text{ d}^{-1}$. Perchlorate administration induced dose-related increases in TSH and decreases in T4 and T3 in both males and females, but females appeared to be more sensitive than males. The lowest administered dose, $0.1 \text{ mg kg}^{-1} \text{ d}^{-1}$, increased TSH and decreased T4 and T3 in females roughly by 15, 12, and 34%, respectively, relative to controls [965].

Fourteen and 90-day exposures of mice to 0, 0.1, 1.0, 3.0, and $30 \text{ mg kg}^{-1} \text{ d}^{-1}$ in drinking water produced no significant changes in thymus weight, thymus cellularity, and thymus to body weight ratio for any of the 14- or 90-day treatments [966]. AP is known to cause hypothyroidism with subsequent increases in TSH and decreases in both circulating T3 and T4. However, the profile obtained in mice exposed to AP was one of no change in TSH and T3, with significant decreases in T4. Histology indicated some pathological effects in the thyroid. AP affected thyroid hormone levels in the serum. The primary effect observed in mice treated with AP was decreased phagocyto-

sis function of peritoneal macrophages. White blood cell count, red blood cell count, hematocrit, hemoglobin were not affected. Body, spleen, liver, thymus, and kidney weights were normal. AP did not alter the susceptibility to infections.

No gross or microscopical alterations were observed in the lungs or heart of rats and there was no sign of hematotoxicity in rats administered AP via drinking water at doses of up to $8.5 \text{ mg perchlorate kg}^{-1} \text{ d}^{-1}$ for up to 90 days [967].

A two-generation reproductive study examined the effects of AP on male and female reproductive systems in rats and on the growth and development of offspring [968]. Adult Sprague-Dawley rats (30/sex/group) were given continuous access to AP in their drinking water at doses of 0, 0.3, 3, and $30 \text{ mg kg}^{-1} \text{ d}^{-1}$. F1 generation rats were given the same AP doses as their respective P1 generation sires and dams beginning at weaning and continuing through the day of sacrifice. Standard reproductive parameters were evaluated; blood was collected for determination of serum TSH, triiodothyronine (T3), and thyroxine (T4) levels. Histopathological examination was conducted on major tissue including the thyroid. No significant changes in developmental parameters were observed. In the F1 generation adult rats, relative thyroid weights were significantly increased in all dose groups for female rats and in the 3.0 and $30 \text{ mg kg}^{-1} \text{ d}^{-1}$ dose groups for male rats. Histopathologic changes in the thyroid consisted of hypertrophy and hyperplasia that increased in incidence and severity in a dose-related manner. Dose-related, statistically significant changes in TSH and T4 or T3 occurred at doses higher than those that resulted in changes in thyroid weight and thyroid histopathology, $30 \text{ mg kg}^{-1} \text{ d}^{-1}$. Thus, perchlorate is not a reproductive toxicant in rats when administered in the drinking water at doses up to 30 mg/kg-day , but it can affect the thyroid at doses $\geq 3 \text{ mg kg}^{-1} \text{ d}^{-1}$. Based on these findings, $0.3 \text{ mg kg}^{-1} \text{ d}^{-1}$ is identified to be the NOAEL for this animal.

Beginning at three to four days post-hatch, bobwhite quail chicks were used to investigate AP effects on thyroid function and growth. The bobwhite quail chicks were administered a wide range of AP concentrations ($50 \mu\text{g/L}$ – 4000 mg/L) in their drinking water for relatively short (two weeks) and longer (eight weeks) exposures [969]. Thyroidal thyroxine (T4) content, the most sensitive index of decreased thyroid function, decreased markedly in response to increasing perchlorate exposure. Thyroid weight and plasma T4 were less sensitive indicators.

Despite many physiological similarities, humans and rats exhibit notably different susceptibilities to thyroid perturbation. While the data indicate that humans and rats exhibit similar dose-response relationships in terms of acute inhibition of thyroidal iodide uptake, the two species appear to exhibit notable differences in terms of thyroid hormone response, the toxicologically significant consequence of iodide uptake inhibition [970]. Comparing dose-response data for changes in serum T3, T4, and TSH levels from studies in humans, rats, mice, and rabbits, it was found that thyroid homeostasis in rats appeared to be strikingly more sensitive to perchlorate than any

of the other species. If rat data is used to develop toxicity criteria for perchlorates in humans, one must remember that the interspecies uncertainty factor is less than one.

In another test, 24 pregnant Long-Evans rats were exposed to either 0, 5, or 50 mg/L AP from GD 7-21 and to **post-natal day** (PND) 24-25 through maternal exposure and lactation [971]. On PND 24-25, female pups were euthanized and ovaries were examined histologically. The number of ovarian (preantral and antral) follicles were reduced in the $4 \text{ mg kg}^{-1} \text{ d}^{-1}$ groups but not in the $0.4 \text{ mg kg}^{-1} \text{ d}^{-1}$ groups. Co-administered T4 ameliorated the effects of perchlorates. No changes in mean ovarian area were observed between treatments.

Triggering of the HPT feedback response in profound iodide deficiency can affect the response of the thyroid to perchlorates. Rats maintained on an iodine-deficient diet for sufficient periods to lower serum T4 levels exhibited higher 24-hour thyroid radioiodide uptake when exposed to perchlorates in their drinking water ($1.1\text{--}28 \text{ mg/L}$) for five weeks than iodine-replete rats [972]. The increased resistance to perchlorate-induced inhibition of thyroid iodide uptake in iodine deficiency has been attributed, at least in part, to an induction of NIS in the thyroid. This partially overcomes the competitive inhibition of NIS resulting from a given dosage of perchlorates (see [973] also).

7.3.2 Thyroid Gland: Controlled Studies With Human Volunteers

Burgi et al. [974] studied perchlorates at a dosage of $9.7 \text{ mg kg}^{-1} \text{ d}^{-1}$ on five subjects for eight days, while Brabant et al. [975] studied perchlorates at a dosage of $12 \text{ mg kg}^{-1} \text{ d}^{-1}$ on five subjects for four weeks. Both studies observed perchlorate effects on the thyroid at these doses and found that it reduced thyroid iodide uptake, increased serum iodide levels, and increased urinary iodide excretion. Inhibition of thyroid iodide uptake is the only effect that has been consistently documented in humans exposed to perchlorate.

As of 1998, only a few studies had examined the effects of perchlorate in healthy volunteers, but within ten years many more study results were published. Studies were carried out in nine healthy male volunteers who had normal thyroid function and negative thyroid antibodies to determine whether the ingestion of 10 mg of ClO_4^- daily (approximately 300 times the estimated maximum amount of ClO_4^- consumed from the affected water supplies) would affect any aspect of thyroid function [976]. The volunteers ingested 10 mg of ClO_4^- dissolved in a liter of spring water during waking hours for 14 days in a row. Baseline serum thyrotropin (TSH), free thyroxine index (FTI), total triiodothyronine (TT3), four-, eight-, and 24-hour thyroid ^{123}I uptakes (RAIU), serum and 24-hour urine ClO_4^- , 24-h urine iodine, complete blood count (CBC), and chemistry profiles were determined. All blood and urine tests were repeated on days seven and 14 of ClO_4^- administration and thyroid radioactive iodine uptake (RAIU) on day 14 of ClO_4^- administration. All tests were repeated 14 days after ClO_4^- was discontinued. No effect of ClO_4^- on serum thyroid hormone or TSH concentrations, urinary

iodine excretion, CBC, or blood chemistry was observed. Urine and serum ClO_4^- levels were appropriately elevated during the course of ClO_4^- ingestion in all subjects, demonstrating compliance. By day 14 of ClO_4^- administration, the four-, eight-, and 24-hour thyroid RAIU values decreased in all nine subjects by a mean value of 38% from baseline and rebounded above baseline values by 25% at 14 days after ClO_4^- withdrawal. It is well-known that the major effect of ClO_4^- on the thyroid is a decrease in the thyroid iodide trap due to competitive inhibition of the sodium/iodide symporter (NIS). The study demonstrated the sensitivity of the thyroid iodide trap to ClO_4^- because a low dose of 10 mg daily significantly decreased the thyroid RAIU without affecting circulating thyroid hormone or TSH concentrations. It is possible, however, that the daily consumption of low levels of ClO_4^- in drinking water over a prolonged period of time could adversely affect thyroid function but no evidence of hypothyroidism was observed at 10 mg of ClO_4^- daily in this two-week study. It was suggested that, to determine a no-effect-level for ClO_4^- on the inhibition of the thyroid RAIU a long-term ClO_4^- exposure study would be required to be carried out.

Application of a sensitive new detection method has revealed widespread perchlorate contamination of groundwater in the southwestern areas of the US, typically at 0.005–0.020 mg/L (5–20 ppb). Perchlorate is a competitive inhibitor of the process by which iodide is actively transported from the bloodstream into the thyroid. This inhibitory action of perchlorate is the basis of its pharmaceutical use (in the treatment of hyperthyroidism) as well as its potential toxicity. In order to establish the dose-response in humans for perchlorate inhibition of thyroidal iodide uptake and any short-term effects on thyroid hormones, perchlorate in drinking water at 0.007, 0.02, 0.1, or 0.5 mg kg⁻¹ d⁻¹ was administered to 37 volunteers for 14 days [977]. In 24 subjects, eight- and 24-hour measurements of thyroidal ¹²³I uptake (RAIU) were taken before exposure. The same was performed on days two (E2) and 14 (E14) and upon day 15 post-exposure (P15). In another 13 subjects, both E2 studies and the eight-hour P15 study were omitted. There was a strong correlation between the eight- and 24-hour RAIU over all dose groups and measurement days. There was no difference between E2 and E14 in the inhibition of RAIU produced by a given perchlorate dose. On both E2 and E14, the dose-response was a negative linear function of the logarithm of dose. Based on the dose-response for the inhibition of the eight- and 24-hour RAIU on E14 in all subjects, estimates of the true no-effect level were derived: 5.2 and 6.4 µg kg⁻¹ d⁻¹, respectively. Given default body weight and exposure assumptions, these doses would be ingested by an adult if the drinking-water supply contained perchlorate at concentrations of approximately 180 and 220 µg/L (ppb), respectively. On P15, RAIU was not significantly different from the baseline. In 24 subjects, serum levels of thyroxine (total and free), triiodothyronine, and thyrotropin were measured in blood sampled 16 times throughout the study. Only the 0.5 mg kg⁻¹ d⁻¹ dose group showed any effect on serum hormones: a slight downward trend in thyrotropin levels in morning blood draws during perchlorate exposure, with recovery by P15. The study identified a no-observed-effect level (NOEL) for inhibition of iodide uptake by the thyroid at 0.007 mg kg⁻¹ d⁻¹.

A study was conducted to determine whether prolonged exposure (six months) to low levels of perchlorate would perturb human thyroid function [978]. This was a prospective, double-blinded, randomized trial. The study population consisted of 13 healthy volunteers. The dosage was 0.5 mg or 3.0 mg potassium perchlorate daily. Serum thyroid function tests, 24-hour radioactive iodine uptake, serum thyroglobulin (Tg), urinary iodine and perchlorate, and serum perchlorate were measured. Mean urinary perchlorate value during the ingestion of 0.5 mg perchlorate daily was $332.7 \pm 66.1 \mu\text{g}$ per 24 hours or $248.5 \pm 64.5 \mu\text{g/g}$ creatinine. Mean values for the four subjects who received 3 mg perchlorate daily were $2079.5 \pm 430.0 \mu\text{g}$ per 24 hours or $1941.7 \pm 138.5 \mu\text{g/g}$ creatinine. There was no significant change in the thyroid ^{123}I uptakes during perchlorate administration. There were no significant changes in serum T3, free T4 index, TSH, or Tg concentrations during the exposure period (compared to baseline or post-exposure values). Urine iodine values for the 3-mg perchlorate group were higher, but not significantly so, at baseline than during perchlorate exposure. It was concluded that a six-month exposure to perchlorate at doses up to 3 mg/d had no effect on thyroid function, including inhibition of thyroid iodide uptake as well as serum levels of thyroid hormones, TSH, and Tg. In summary, the duration of the studies of potassium perchlorate administration in healthy subjects varied from two weeks to six months. In all these studies, there were no changes in serum T4, T3, and TSH concentrations to suggest that there had been any decrease in thyroid hormone secretion. Some doses of perchlorate administered for two weeks did inhibit thyroid uptake of radioiodide. A high dose administered for four weeks lowered thyroid iodide content by 25%, indicating some decrease in iodide uptake [975], and resulted in a very small fall in serum-free T4 concentrations. However, serum TSH concentrations were also lower rather than higher, as would occur if serum-free T4 concentrations decreased to a critical extent.

There has been concern that naturally occurring perchlorate and industrial contamination of water supplies with perchlorate might pose a health hazard by inducing or aggravating underlying thyroid dysfunction. A series of studies have been conducted with normal volunteers. Volunteers included perchlorate production workers exposed intermittently to high levels of perchlorate for years and human volunteers administered perchlorate for between two weeks to six months. No abnormalities of circulating thyroid hormones, TSH, thyroglobulin, or ultrasound evaluation of thyroid structure were observed even though the thyroid ^{123}I uptake was decreased in some studies [979]. Further studies of the effects of perchlorates on thyroid function in normal volunteers have become more difficult to carry out due to the adverse publicity that perchlorate and the studies on its effect have received.

7.3.3 Thyroid Gland Function in Workers Occupationally Exposed to Perchlorates

Employees at an AP production facility in Nevada and a larger control population from the same chemical complex without direct AP exposure were monitored exten-

sively for airborne perchlorate exposure [980]. Single-shift and working-lifetime cumulative dose estimates were made using standard breathing-rate estimates and assuming rapid absorption, based upon solubility. Calculated single-shift doses ranged from 0.2 to 436 $\mu\text{g}/\text{kg}$, with an average of 36 $\mu\text{g}/\text{kg}$. Working-lifetime cumulative doses in the higher exposure group ranged from 8000 to 88000 $\mu\text{g}/\text{kg}$, with an average of 38000 $\mu\text{g}/\text{kg}$. Thyroid profiles, including free thyroxine index and TSH level, were obtained both before and after shifts to assess thyroid-axis perturbation due to single working-shift perchlorate exposure. Thyroid-function data were also analyzed with respect to estimates of cumulative exposure to assess any measurable chronic effects on thyroid gland function. Additionally, standard clinical blood test parameters of liver, kidney, and bone marrow function were evaluated to assess any measurable chronic effects of perchlorate exposure on those organs. Multiple regression was used to assess the effects of exposure variables and demographic variables on organ function parameters. No perchlorate-attributable effects on the thyroid, bone marrow, kidney, or liver function were detected.

Since pharmaceutical exposures to perchlorate are known to suppress thyroid function in patients with hyperthyroidism, a study of employees at a perchlorate manufacturing plant was conducted to assess whether occupational exposure to perchlorate suppresses thyroid function [981]. Exposure to perchlorate was assessed using measurements of ambient air concentrations of total and respirable perchlorate particles. Systemic absorption was assessed by measuring urinary perchlorate excretion. Airborne exposures ranged from 0.004 to 167 mg total particulate perchlorate per day. Urinary perchlorate measurements demonstrated that exposure to the airborne particulate perchlorate resulted in systemic absorption. Workers were grouped into four exposure categories with mean absorbed perchlorate dosages of 1, 4, 11, and 34 mg perchlorate per day. Thyroid function was assessed by measuring serum TSH, free thyroxine index, thyroxine, triiodothyronine, thyroid hormone binding ratio, thyroid peroxidase antibodies, and via clinical examination. No differences in thyroid function parameters were found between the four groups of workers across approximately three orders of magnitude of exposure and of dose. Thus, human thyroid function was not affected by these levels of absorbed perchlorate. In addition, no clinical evidence of thyroid abnormalities was found in any exposure group. The blood-cell counts were normal in all groups, indicating no evidence of hematotoxicity in this exposure range. The absence of evidence of an effect on thyroid function or blood cells from occupational airborne perchlorate exposure at a mean absorption of 34 mg/d demonstrates a NOAEL that can assist in the evaluation of human health risks from environmental perchlorate contamination.

Perchlorate and thiocyanate (SCN^-) are potent and nitrate a weak competitive inhibitor of the thyroid sodium/iodide symporter. Thiocyanate is not likely to occur in the air of perchlorate factories and can be ignored here. To determine the effects of long-term, high ClO_4^- exposure on thyroid function, a study of 29 workers employed for at least 1.7 years (50% over 5.9 years) in an AP production plant in Utah was con-

ducted [982]. The cohort was divided into three groups: Pre, During and C. Serum ClO_4^- , SCN^- , and NO_3^- ; serum T4, free T4 index, total T3, thyroglobulin (Tg), and TSH; 14-hour thyroid RAIU; and urine iodine (I) and ClO_4^- were assessed after three days off (Pre) and during the last of three 12-hour night shifts in the plant (During) and in 12 volunteers (C) not working in the plant. Serum and urine ClO_4^- were not detected in C; urine ClO_4^- was not detected in 12 of 29 and was 272 $\mu\text{g/L}$ in 17 Pre workers; serum ClO_4^- was not detected in 27 of 29 Pre workers; and serum and urine ClO_4^- were markedly elevated during ClO_4^- exposure to 868 $\mu\text{g/L}$. Thyroid RAIUs were markedly decreased in During compared to Pre workers (13.5 versus 21.5%; $P < 0.01$, paired t) and were associated with an increase in urine I excretion (230 versus 148 $\mu\text{g I/g Cr}$; $P = 0.02$, paired t) but were similar to those in the C group (14.4%). Serum TSH and Tg concentrations were normal and similar in the three groups. Serum T4 (8.3 versus 7.7 $\mu\text{g/dL}$), free T4 index (2.4 versus 2.2), and total T3 (147 versus 134 ng/dL) were slightly but significantly increased in the During versus Pre workers ($P < 0.01$, paired t). Thyroid volumes and patterns observed using ultrasound were similar in the 29 workers and 12 community volunteers. In conclusion, high ClO_4^- absorption during three nights work exposure decreased the 14-hour thyroid RAIU by 38% in ClO_4^- production workers compared with the RAIU after three days off. However, serum TSH and Tg concentrations and thyroid volume observed using ultrasound were not affected by ClO_4^- , suggesting that long-term, intermittent, high exposure to ClO_4^- does not induce hypothyroidism or goiter in adults.

The National Research Council AP report [983] contains a very detailed summary of the epidemiological and occupational studies and an interpretation of the results. Particular focus is given to vulnerable populations, including pregnant women and children.

7.4 Epidemiological Studies of Unintended Exposure to Perchlorates

Epidemiological studies have been performed on populations living near natural sources of perchlorate (and nitrate) in the groundwater or populations who live downstream of industrial sites where the amount of perchlorate contamination was being monitored for several years while corrective or mitigative action was being taken.

7.4.1 Epidemiological Studies in the US

Model-based exposure assessment is one of the least reliable methods in establishing a link between environmental exposure and health effects. The accuracy and precision of exposure assessments can be improved by simultaneous environmental monitoring and human biological monitoring, or biomonitoring [984]. Biomonitoring quantifies exposure by directly measuring the contaminant (perchlorate) in human

matrices such as blood, urine, saliva, or other tissue. The direct measurement of a biomarker proves irreputably that an exposure has occurred. Such calculations are reliable for perchlorate because most of the perchlorate is excreted unmetabolized in the urine [333].

The results of perchlorate exposure in a representative sample of the US population were compared to the NAS-recommended RfD [985]. The study comprised of 2820 participants who had completed the National Health and Nutrition Survey (2001–2002) and were above six years of age. The investigators assessed perchlorate exposure based on urinary perchlorate, urinary creatinine concentration, and physiological parameters predictive of creatinine excretion rate. By measuring perchlorate in urine, the investigators assessed combined exposure to perchlorate from all sources. In adults, the estimated median dose of perchlorate was $0.066 \mu\text{g kg}^{-1} \text{d}^{-1}$ and the 95th percentile of the distribution of estimated daily dose was $0.234 \mu\text{g kg}^{-1} \text{d}^{-1}$ (CI, $0.202\text{--}0.268 \mu\text{g kg}^{-1} \text{d}^{-1}$). Both values are lower than the MRL of $0.0007 \text{mg kg}^{-1} \text{d}^{-1}$ ($0.7 \mu\text{g kg}^{-1} \text{d}^{-1}$) that ATSDR adopted from the NAS. Only 11 out of 1532 adults aged twenty and older had estimated perchlorate exposure that exceeded the NAS-recommended RfD. Since the study included participants above six years of age, the investigators did not have exposure information for infants. In women of reproductive age, the median estimated perchlorate dose was $0.057 \mu\text{g kg}^{-1} \text{d}^{-1}$ and the 95th percentile $0.214 \mu\text{g kg}^{-1} \text{d}^{-1}$. For a subset of 110 pregnant women, the estimated median perchlorate dose was $0.066 \mu\text{g kg}^{-1} \text{d}^{-1}$. The median dose of $0.066 \mu\text{g kg}^{-1} \text{d}^{-1}$ for adults is in the same range of the lower-bound range of average perchlorate food intakes for men and women over 20 years of age of $0.08\text{--}0.11 \mu\text{g kg}^{-1} \text{d}^{-1}$. This dose was estimated by the Food and Drug Administration (FDA) in the Total Diet Study (TDS) [986]. These data provided the first thorough population-based assessment of the magnitude and prevalence of perchlorate exposure in the US.

The levels of three physiologically relevant NIS-inhibitors (perchlorate, nitrate, and thiocyanate) and iodide in maternal and fetal fluids collected during cesarean-section surgeries on 150 women from the US were measured [987]. The geometric means of perchlorate levels in maternal urine ($2.90 \mu\text{g/L}$) were similar to previously published results. Perchlorate was detected in most samples: urine (100%), maternal serum (94%), cord serum (67%), and amniotic fluid (97%). Maternal urinary perchlorate levels were positively correlated with perchlorate levels in amniotic fluid ($r=0.57$), indicating that maternal urine perchlorate is an effective biomarker of fetal perchlorate exposure. There was no evidence of either disproportionate perchlorate accumulation or lack of iodide in the fetal compartment. In this panel of healthy infants, there was no association between cord blood levels of these anions and newborn weight, length, and head circumference.

Any condition, such as genetic abnormality or inherited susceptibility affecting processes by which circulating iodide ultimately becomes part of a functional thyroid hormone, will increase the susceptibility to substances that affect thyroid function such as perchlorate. Among these conditions are genetic factors [988,

989]. Increased susceptibility to perchlorate can also result from defects in iodide organification, a process by which iodide is oxidized and bound to thyrosine residue in thyroglobulin.

All studies investigating possible adverse effects of environmental perchlorate exposure on thyroid function in adults or in pregnant women and their newborns were critically evaluated. It was concluded that there is no credible or consistent evidence from any of the numerous studies (that used a variety of designs) that environmental exposure to perchlorate has any adverse effect on thyroid function whether measured as changes in thyroid hormone levels or, among newborns, as the diagnosis of primary congenital hypothyroidism [990]. The absence of adverse effects of environmental perchlorate on the thyroid reflects the very low perchlorate exposure levels worldwide, compared with much higher levels of exposure to nitrate and thiocyanate, goitrogens that inhibit thyroid function via an identical mechanism of action proposed for perchlorate. Adjusted for potency, perchlorate accounts for <1% of the inhibition of iodide uptake in the thyroid resulting from environmental exposure to nitrate and thiocyanate. Occupational studies of workers with substantially higher perchlorate exposure than the general population indicate that even extended exposure to high perchlorate levels did not adversely affect thyroid function. There is no epidemiologic evidence that environmental or occupational exposure to perchlorate adversely affects thyroid function in the US. Even if all perchlorate could be removed from the environment, more than 99% of the inhibition of iodide uptake in the thyroid resulting from exposure to environmental goitrogens would remain.

7.4.2 Other Epidemiological Studies in North America

One-hundred-and-fifty food samples of imported and domestic fruits and vegetables available from retail outlets in Ottawa, Canada, were analyzed using ion chromatography tandem mass spectrometry (IC-MS/MS) to determine the concentrations of perchlorate [991]. Perchlorate was found in most of the tested food types with concentrations appearing to vary by commodity and country of origin. Levels ranged from non-detectable to 536 µg/kg, with Guatemalan cantaloupes (156 ± 232 µg/kg), spinach from the US (133 ± 24.9 µg/kg), Chilean green grapes (45.5 ± 13.3 µg/kg), and Romaine lettuce from the US (29.1 ± 10.5 µg/kg) having the highest concentrations. Dietary exposure to perchlorate from analyzed fruits and vegetables was estimated to be approximately 36.6 and 41.1 ng/kg body weight/day for toddlers (1–4-years-old) and children (5–11-years-old), respectively.

7.4.3 Epidemiological Studies in South America

Perchlorates are a natural contaminant in nitrate deposits that have been mined in South America for several centuries. Most of the nitrates mined were used as fertilizer. Particular emphasis has been placed on studying potential perchlorate effects in contaminated areas on pregnant women and their babies.

A group of 184 pregnant women and their newborns in northern Chile were evaluated for neonatal weight, length, head circumference, gestational length, and FT4, T3, thyroglobulin, and ClO_4^- in cord serum. The evaluation showed no significant differences between the three cities regarding indicators of fetal development or in FT4 or TSH. T3 and thyroglobulin were significantly lower among neonates from Chañaral (low perchlorate, 5.8 $\mu\text{g/L}$) than in the other two cities [992]. This epidemiologic study on public drinking water, which examined pregnant women from three cities in northern Chile (Taltal with 114 $\mu\text{g/L}$, Chañaral with 6 $\mu\text{g/L}$, and Antofagasta with 0.5 $\mu\text{g/L}$ ClO_4^-) was done to test the hypothesis that long-term exposure to perchlorate at these levels may cause a situation analogous to iodine deficiency. This could cause increases in thyrotropin (TSH) and thyroglobulin (Tg) levels and decreased levels of free thyroxine (FT4) in either the mother during the early stages of gestation, in the neonate at birth, or in the fetus where it may cause growth retardation. There were no increases in Tg or TSH and no decreases in FT4 that could be related to perchlorate concentration in the drinking water among either the women during early pregnancy (16.1 ± 4.1 weeks), late pregnancy (32.4 ± 3.0 weeks), or the neonates at birth. Neonatal birth weight, length, and head circumference were not different among the three cities and were consistent with current US norms. Therefore, it was concluded that perchlorate in drinking water at 114 $\mu\text{g/L}$ does not cause changes in neonatal thyroid function or fetal growth retardation.

In an often-quoted study that is considered as reliable, Crump et al. [993] conducted a study of school-age children from three cities in northern Chile with different concentrations of perchlorate in drinking water [993]. The city with the highest perchlorate concentration was Taltal, 100–120 $\mu\text{g ClO}_4^-/\text{L}$ (ppb). The study comprised of 162 children between the ages of 6 and 8-years-old, of which 127 had resided continuously in their respective cities since conception. The children underwent examination of the thyroid gland and a blood sample was taken for analysis of TSH, T4, FTI, T3, and anti-peroxidase antibody. After adjusting for sex, age, and urinary iodide excretion, the children from Taltal and Chañaral had slightly lower TSH levels than children from Antofagasta (which was opposite to what would be expected), but the differences were not statistically significant. Serum T4 levels in the city with the highest perchlorate levels were significantly higher than in the city with no perchlorate (which was also opposite to what would be expected). Analysis of all of the children included in the study revealed a small non-significant increased risk of goiter in the cities with perchlorate compared with the city without perchlorate, however, there was virtually no difference in risk when only lifelong residents were analyzed. The study also found that lifelong residents of Taltal (high perchlorate) were >5 times more likely to report a family history of thyroid disease compared with lifelong residents of Antofagasta (no perchlorate). Assuming a reference daily consumption of water of 1–2 L and using body weight for the children of approximately 25 kg (measured in the study), a concentration of ClO_4^- in the drinking water of 100 $\mu\text{g/L}$ would provide doses of

approximately $0.004\text{--}0.008\text{ mg ClO}_4^- \text{ kg}^{-1} \text{ d}^{-1}$ via drinking water alone. Notably, the Chilean population also has additional large dietary sources of perchlorate.

The same study [993] also evaluated TSH levels in neonates from the three aforementioned cities in northern Chile. A total of 9784 neonatal records were analyzed for TSH levels, sex, and date of screening for infants born between February 1996 and January 1999. The study did not control for iodine intake, ethnicity, or birth weight. The rate of congenital hypothyroidism detected in Chile from 1992 to 1999 was 1 per 3484 cases (based on 773440 newborns screened). In their study, Crump et al. [993] detected seven cases of presumptive congenital hypothyroidism corresponding to a rate of 1 per 1270 newborns. All of these cases originated in the city with no detectable levels of perchlorate. Linear regression comparisons of TSH by city demonstrated a statistically significant decline in TSH with increasing perchlorate concentration in the drinking water, which is opposite to the known effect of perchlorate. The magnitude of the differences in TSH concentrations did not seem to be clinically significant.

7.4.4 Epidemiological Studies in Asia

Perchlorate concentrations in Japanese dairy milk samples ranged from 5.47 to $16.40\text{ }\mu\text{g/L}$ with a mean value of $9.39\text{ }\mu\text{g/L}$ and a median value of $9.34\text{ }\mu\text{g/L}$ [994].

The concentration of perchlorate in rice, bottled drinking water, and milk collected in China was in the range of $0.6\text{--}380\text{ }\mu\text{g/kg}$, $0.16\text{--}4.9\text{ }\mu\text{g/kg}$, $0.04\text{--}2\text{ }\mu\text{g/L}$, and $0.3\text{--}9\text{ }\mu\text{g/L}$, respectively [995]. The results showed that perchlorate pollution has been widespread in China but the sources are uncertain.

7.5 Correlations Between Perchlorate in Drinking Water and Thyroid Gland Function

There has been a lot of concern about the effect of perchlorate in drinking water on the thyroid function of the population at large and, in particular, in newborns and children [993]. Although there has been no nationwide sampling for perchlorate recently, nationwide sampling under the EPA's Unregulated Contaminant Monitoring Rule 1 (UCMR 1), which was in force between 2001 and 2005, detected perchlorate at or above 4 ppb in at least one sample in approximately 4.1% of all the public drinking water systems tested. According to EPA data, perchlorate was reported in 160 of 3865 public drinking water systems, with detections ranging from 4 to 420 ppb. Thirty-one of the 160 systems, or about a fifth, had detections above 15 ppb, which is the EPA's current interim drinking water health advisory level. Based on EPA monitoring conducted from 2001 to 2005, 153 drinking water sources in 26 states were found to contain perchlorate. In Riverside and San Bernardino, CA, some drinking water wells contain up to $216\text{ }\mu\text{g/L}$ and nine wells have been closed in this area.

The DOD reported perchlorate detections at 284 of its installations, or almost 70% of the 407 installations sampled from fiscal years 1997 through 2009, with detections ranging from less than 1 ppb to 2.6 million ppb. Maximum detection in parts per billion included 30 in drinking water, 230 in sediment, 6600 in surface water, 786000 in soil, and 2600000 in groundwater. Fifty-three of the 284 installations, or about 20%, reported perchlorate concentrations above 15 ppb.

The southwestern areas of the US are facing a drought and water shortage due to climate changes, overpopulation, irresponsible real estate speculation without adequate infrastructure, and geological/hydrological limitations. Aquifers do not remain filled forever. In this situation, any loss of potential water sources due to groundwater contamination is a severe blow to the local economy. In 2003, California agreed to reduce its water intake from the Colorado River by 20%. With less Colorado River water available, the dependence on groundwater sources have increased, and any contamination in groundwater sources is a serious problem. In California, 43% of the drinking water comes from groundwater supplies [996].

Data from neonatal screening programs of the state health departments in California and Nevada were analyzed statistically for any increased incidence of congenital hypothyroidism [997]. County-specific, ethnicity-specific data for Nevada and California were obtained for 1996 and 1997. Within seven counties, nearly 700000 newborns had been screened. In total, 249 cases were identified (243 were expected) for an overall risk ratio of 1.0 (95% confidence interval, 0.9 to 1.2). The risk ratios for the individual counties ranged between 0.6 and 1.1. These data do not indicate an increase in the incidence of congenital hypothyroidism with the reported perchlorate levels of 4 to 16 $\mu\text{g/L}$.

A study of newborn TSH levels compared TSH levels between two cities in Arizona, Yuma and Flagstaff. These two areas represented areas of exposure and non-exposure, respectively [998]. The study covered a three-year period between October 1994 and December 1997. The final analysis comprised of 1099 newborns from Yuma and 443 from Flagstaff. The study controlled for age at screening and Hispanic ethnicity, but not for gender, gestational age, or birth weight. The median first TSH level in Yuma was significantly higher than in Flagstaff (19.9 $\mu\text{g/L}$ versus 13.4 $\mu\text{g/L}$). These results were not confirmed in a later critical review [999].

The concentrations of perchlorate measured in six water supply wells that serve the city of Loma Linda, CA, during 1997–1998 ranged from <4 to 29 $\mu\text{g/L}$ [1000].

Perchlorate accumulation above 0.5 $\mu\text{g/L}$ was detected in 179 out of 254 public water systems and private wells in nine counties in the Texas Southern High Plains. Perchlorate concentrations were >4 $\mu\text{g/L}$ in 88 wells [1001]. The maximum concentrations were 58.8 $\mu\text{g/L}$ for private wells and 45.6 $\mu\text{g/L}$ for public water system wells.

Perchlorate and nitrate are both goitrogens, i.e., agents that can prevent the thyroid from absorbing iodide. Data from the California Department of Health Services Division of Drinking Water and Environmental Monitoring database of source water monitoring results were analyzed. These indicated that nitrate occurred in signifi-

cantly higher concentrations than perchlorate (and over a much broader geographic area) and co-occurred with perchlorate [1002]. Drinking water sources that contained detectable levels of perchlorate had, on average, much higher concentrations of nitrates. Before taking corrective action, one must first determine if these contaminants share a common source or infiltration route.

The prevalence of perchlorate in drinking water was analyzed and mapped by compiling data from existing perchlorate occurrence surveys [1003]. The existing surveys included studies conducted by utilities and by the states of Arizona, California, Massachusetts, and Texas. Perchlorate was detected in 26 states, Puerto Rico, and the Mariana Islands and was found in at least one source of approximately 5% of the nation's large (>10000 population) public water systems. When found, perchlorate was typically present at concentrations of <12 µg/L. Some water utilities that detected perchlorate have discontinued the use of perchlorate-contaminated sources. On the basis of the results of a 2007 phone survey, it was estimated that at least 50 million gallons per day of potable water production had been taken offline as a result of perchlorate contamination.

Estimates of perchlorate intake by the population of the US can be derived from either urinary excretion data or through simulation of dietary intake. Estimates from surveys of urinary excretion (National Health and Nutrition Examination Survey, NHANES) are subject to substantial uncertainty owing to the small numbers of subjects for which data is currently available. In addition, current excretion estimates are derived from "spot" urine samples and include an uncertainty component of short-term (intra-day) variability that may give biased estimates of the variability in average daily intakes. Using statistical analysis, it was found that including the drinking water contributions in the dietary simulations yields increases in the population's geometric mean perchlorate intake of 3–8%, with a conservative maximum of about 24%, compared to intakes estimated based on food intake alone [1004]. The analyses indicated that a reasonable upper-bound estimate for the 95th percentile perchlorate intake among women of reproductive age in the US is on the order of $1.5 \times 10^{-4} \text{ mg kg}^{-1} \text{ d}^{-1}$.

The extent of perchlorate contamination of drinking water becomes evident if one places all well locations on a map, as has been done for the State of California (Figure 45) (see [1005] also).

7.5.1 Drinking Water Studies Outside the US

7.5.1.1 Drinking Water Studies in Asia

Perchlorate in the Tone River Basin in Japan was analyzed using IC/MS. Perchlorate was found at high concentrations in the upper Tone River and its tributary, Usui River. The maximum concentrations were 340 and 2300 µg/L, respectively [1007]. The sources of perchlorate in the two areas were attributed to industrial effluents. In the case of the upper Tone River, perchlorate concentration in an effluent was 1100 µg/L

Figure 45: Perchlorate contamination detected in public wells (from [1006]).

and its concentrations in a tributary directly downstream of the outlet of the effluent ranged from 44 to 1500 $\mu\text{g/L}$. In the case of the Usui River, perchlorate concentration in another effluent was 15000 $\mu\text{g/L}$ and its concentrations downstream of the outlet of the industrial effluent were 1100–3900 $\mu\text{g/L}$. Perchlorate concentrations in 27 tap water samples were 0.06–37 $\mu\text{g/L}$. Perchlorate concentrations were more than 1 $\mu\text{g/L}$ in 19 tap water samples and more than 10 $\mu\text{g/L}$ in 13 tap water samples. In summary, it was found that tap water from the Tone River Basin was widely contaminated with perchlorate.

Perchlorate levels in drinking water in India were not known until water samples were collected from 13 locations in six states ($n = 66$) and saliva samples were collected from four locations in three states ($n = 74$). These were analyzed for perchlorate using high-performance liquid chromatography (HPLC) interfaced with tandem mass spectrometry (HPLC-MS/MS) [1008]. Perchlorate was detected in most (76%) of the water samples analyzed at concentrations above the quantitation limit of 0.02 $\mu\text{g/L}$. Con-

concentrations ranged from <0.02 to $6.9\text{ }\mu\text{g/L}$ (mean: $0.42 \pm 1.1\text{ }\mu\text{g/L}$; median: $0.07\text{ }\mu\text{g/L}$). Mean concentrations of perchlorate in drinking water, groundwater, bottled water, surface water, and rainwater were 0.1, 1.0, <0.02 , 0.05, and $<0.02\text{ }\mu\text{g/L}$, respectively. From a total of 66 water samples analyzed, only three samples contained perchlorate levels above $1\text{ }\mu\text{g/L}$; all three were groundwater samples. Perchlorate was found in the saliva samples analyzed at concentrations above $0.2\text{ }\mu\text{g/L}$ and up to $4.7\text{ }\mu\text{g/L}$ (mean: $1.3 \pm 1.3\text{ }\mu\text{g/L}$; median: $0.91\text{ }\mu\text{g/L}$). Perchlorate concentrations in water samples from India are one to two orders of magnitude lower than the concentrations reported for the US.

Three hundred water samples were collected from 15 locations in 13 provinces and municipalities of mainland China. These were analyzed for the presence of perchlorate [1009]. In addition to this, other inorganic anions that commonly occur in water (such as iodide, bromide, and nitrate, and the disinfection byproducts bromate, chlorate and, chlorite) were determined using HPLC interfaced with tandem mass spectrometry. Perchlorate was detected in 86% of the samples analyzed at concentrations ranging from <0.02 to $54.4\text{ }\mu\text{g/L}$ (mean $\pm$ SD $2.20 \pm 6.39\text{ }\mu\text{g/L}$; median $0.62\text{ }\mu\text{g/L}$). Mean concentrations of perchlorate in tap water, groundwater, surface waters, and bottled water were 2.46, 3.04, 2.82, and $0.22\text{ }\mu\text{g/L}$, respectively. Significant positive correlations were found between the concentrations of perchlorate and nitrate as well as perchlorate and chlorate.

7.5.1.2 Drinking Water Studies in Europe

Monitoring of 20 raw and treated drinking water sites in England and Wales, away from known missile production or test operations and covering four seasonal periods, revealed that perchlorate is a low-level background contaminant of raw and treated drinking water [1010]. Low concentrations (treated drinking water: <0.020 – $2.073\text{ }\mu\text{g/L}$, mean $0.747\text{ }\mu\text{g/L}$) were detected at every higher-risk site. The concentrations were comparable in each of the four sampling exercises and no significant trends were apparent relating to the time of year, the type of risk, or the method of chlorination.

7.6 Correlations Between Perchlorate in Food Stuff and Thyroid Gland Function

7.6.1 Total Diet Studies

The Department of Agriculture in the US has been funding several studies on the prevalence of perchlorate in foodstuff. Current research and results can be searched at <http://cris.csrees.usda.gov/search.html>.

The most comprehensive study of perchlorate in food is contained in the FDA's 2006 TDS [1011]. This found perchlorate in 74% of the 285 food items tested across the country. These food items represent the major components of the American diet, such as dairy, meat, fruits, and vegetables. Certain foods, such as tomatoes and spinach, had higher perchlorate levels than others. In each of the four geographic regions of

the US (West, North Central, South, and Northeast), the FDA took samples of each of the 285 food items. Of these items, 211 had perchlorate in at least one of the samples.

Now that the omnipresence of perchlorate (even that predating the rocket propellant environmental pollution) has been recognized, one will want to know how much perchlorate is in a normal diet and if the normal diet contains sufficient iodide to prevent any perchlorate-induced hypothyroidisms.

The FDA has conducted the TDS since 1961. It is designed to monitor the food supply in the US for chemical contaminants, nutritional elements, and toxic elements. After 2007, perchlorate was included in TDS sampling and analysis. Intake estimates of perchlorate and iodine, a precursor to iodide, were provided for population groups using the analytical results from the TDS [986]. Estimated average perchlorate and iodine daily intakes, as well as the contribution of specific food groups to total intakes, were estimated for 14 age/sex subgroups of the population of the US. The estimated smallest lower bound to the largest upper bound average perchlorate intakes by the 14 age/sex groups ranged from 0.08 to $0.39 \mu\text{g kg}^{-1} \text{d}^{-1}$, compared with the EPA RfD of $0.7 \mu\text{g kg}^{-1} \text{d}^{-1}$. Infants and children demonstrated the highest estimated intakes of perchlorate on a bodyweight basis. The estimated average iodine intakes of the 14 age/sex groups revealed a lower bound (ND = 0) and upper bound (ND = LOD) range of average intakes from 138 to $353 \mu\text{g person}^{-1} \text{d}^{-1}$. Estimated iodine intakes of infants that are six to 11 months old exceeded their adequate intake. Intakes by children and adult age/sex groups exceeded their relevant estimated average requirement.

A preliminary estimation of perchlorate dietary exposure was performed based on the FDA's 2004/2005 exploratory data. The FDA's Center for Food Safety and Applied Nutrition (CFSAN) estimated human exposure to perchlorate through the consumption of 27 foods and beverages for which CFSAN has collected data (on perchlorate levels) [1012, 1013]. Data sources for the 27 foods and beverages were from exploratory surveys conducted by the FDA in Fiscal Years (FY) 2004 and 2005. These exploratory surveys were conducted in regions where water sources were known to be contaminated with perchlorate and thus the perchlorate levels are likely biased and on the high side. Although the exploratory and limited nature of the surveys did not allow the FDA to provide a representative exposure assessment, the FDA conducted this preliminary exposure assessment because of significant public interest in the issue of perchlorate exposure from food. The FDA planned to update a comprehensive and nationally representative exposure assessment periodically. In the list of 27 food items, the highest perchlorate concentrations were found in spinach (115 pp), "greens" (lettuce?) (92.4 ppm), cantaloupe (28.6 ppm), and shrimp (19.8 ppm). Averaging the estimated total mean population (all persons aged two and above) for a normal diet showed the perchlorate exposure from the 27 foods and beverages to be $0.053 \mu\text{g/kg bw/day}$, which is below the RfD of $0.7 \mu\text{g/kg bw/day}$ recommended by NAS and adopted by the EPA.

In addition to diet studies covering the entire population, specific diet studies were directed at the diet intake of infants from commercial baby formula products [1014]. Perchlorate exposure may be higher in infants compared with older

persons due to bodyweight to food intake weight ratios. A quantitative assessment of perchlorate concentrations in commercially available powdered infant formulas was done to estimate the exposure in infants under different dosing scenarios, then to compare them with the perchlorate RfD. The perchlorate RfD may be exceeded when certain bovine milk-based infant formulas are ingested and/or when they are reconstituted with perchlorate-contaminated water.

7.6.2 Perchlorate in Vegetables

Perchlorate content in 11 edible cantaloupe and ten whole cantaloupe samples was median (range) 9.6 (<2.0–18.2) and 23.9 (<2.0–39.3) $\mu\text{g}/\text{kg}$, respectively (fresh/dry weight not specified) [334].

Perchlorate concentrations in lettuce irrigated with Colorado River water (5 mg/L perchlorate concentration) ranged from below quantifiable levels to 142 $\mu\text{g}/\text{kg}$ (fresh weight) in the total above ground plant, 195 $\mu\text{g}/\text{kg}$ (fresh weight) in the frame and wrapper leaves, and below detection to 26 $\mu\text{g}/\text{kg}$ (fresh weight) in the edible head [1015].

Perchlorate was detected above 0.2 $\mu\text{g}/\text{L}$ in 144 out of 438 leafy vegetable samples produced and sampled in California (outside the Colorado River region), Colorado, New Jersey, New Mexico, New York, Michigan, Ohio, and Quebec [1016]. Quantifiable perchlorate concentrations ranged from 18 to 104 $\mu\text{g}/\text{kg}$ fresh weight in conventionally grown vegetables and from 21 to 628 $\mu\text{g}/\text{kg}$ fresh weight in organically grown vegetables (see [1017, 1018] also).

Citrus fruit grown on trees in the Southwest that were irrigated with perchlorate contaminated water (mean concentration of approximately 6 $\mu\text{g}/\text{L}$) contained mean, median, and maximum perchlorate concentrations of 2.3, 1.3, and 14.8 $\mu\text{g}/\text{L}$ fresh weight, respectively, in 33 lemon samples. Similar results were 3.3, 1.3, and 16.2 $\mu\text{g}/\text{L}$ fresh weight, respectively, in 15 grapefruit samples, and 7.4, 4.8, and 37.6 $\mu\text{g}/\text{L}$ fresh weight, respectively, in 28 orange samples [1019].

The Colorado River is the primary source of irrigation water for most food crops grown in Southern California and Southwestern Arizona. A comparison of perchlorate levels in broccoli, cauliflower, and cabbage grown in fields irrigated with water from the Colorado River, which contains perchlorate (with levels of thiocyanate and nitrate, which are two other anions that also inhibit iodide uptake) led to the conclusion that brassica irrigated with Colorado River water does indeed accumulate trace levels of perchlorate. However, the levels of perchlorate observed are much lower than the levels of nitrate and thiocyanate, which are naturally present in these vegetables and which may also affect the thyroid gland [1020].

The major food commodities in addition to vegetables produced in the region were sampled and perchlorate levels were determined by using ion chromatography followed by detection using either conductivity or tandem mass spectrometry depending on analyte levels [1021]. Perchlorate exposure estimates derived in this study were

comparable to exploratory estimates found by the FDA. For infants and children, over 50% of the estimated perchlorate exposure was from milk. The relative impact of vegetables and fruit toward perchlorate exposure increased by age through adulthood. Cumulative perchlorate exposure estimates based on this hypothetical analysis could approach or exceed the NAS RfD for some population groups but only where drinking water levels exceeded 6 µg/L. However, few individuals are exposed to perchlorate in drinking water at levels above 4 µg/L in the US and very few would be exposed to perchlorate levels exceeding the RfD, whether consuming food crops from within or outside the lower Colorado River region.

Perchlorate's adverse effects would be less severe if there is sufficient iodine in the diet. Most studies have only evaluated the uptake and distribution of ClO_4^- by plants without considering the potential for concurrent uptake of iodine by the plant and the subsequent impacts on ClO_4^- and iodine uptake and distribution on human health. When studying the relative uptake of ClO_4^- and I supplied as either KI or KIO_3 in butter head lettuce, it was found that if lettuce is grown using fertilizers containing both ClO_4^- and I^- , then the final ratio of $\text{I}^-/\text{ClO}_4^-$ in the leaves will be essentially equal to the ratio in the fertilizer but lower if the I is supplied as IO_3^- [1022]. Therefore, the impact of the consumption of lettuce containing ClO_4^- may be mitigated if the lettuce is grown using fertilizer with an appropriate amount of I to maintain the existing ratio of serum I to total goitrogen load.

7.6.3 Perchlorate in Meat and Milk

Perchlorate exposure and its potential effects were evaluated in beef cattle by monitoring heifer calves placed on a site with the only access to water being from a perchlorate-contaminated groundwater spring (25 ng/mL) [1023]. Blood was collected from two calves on the site (and two control calves from an uncontaminated site) approximately every two weeks for analysis of perchlorate residues and thyroid hormones. During the 14-week study, perchlorate was detected (D.L. = 13.7 ng/mL) in blood plasma twice (15 ng/mL and 22 ng/mL). Constant exposure to 25 ppb perchlorate in drinking water had no effect on circulating thyroid hormones (T3 and T4) in the heifer calves.

It has been attempted to categorize the sources of perchlorate found in our daily food intake, depending on the geographical area where we live [1024].

It was estimated that infants breastfed for six months may have daily doses of perchlorate that exceed the NAS recommended RfD of $0.7 \mu\text{g kg}^{-1} \text{d}^{-1}$ [1025].

Cattle that are fed with grass grown in pastures that are irrigated with contaminated water will pass the perchlorate into the milk. It has been attempted to establish a correlation between the contamination of the feed and the perchlorate content of the milk [1026]. Based on a nine-week long experiment in which 16 dairy cows were administered perchlorate, an equation was derived for the dose-response relationship between perchlorate concentrations in feed/drinking water and its appearance in

milk. Examination of background concentrations of perchlorate in the total mixed ration (TMR) fed in addition to the variable dose supplied to treated cows as a ruminal infusate revealed that cows receive significant and variable exposure to perchlorate from the TMR. Weekly examination of the TMR disclosed that a change in ingredients midway through the experiment caused a significant (78%) change in TMR perchlorate concentration. Analyses of the ingredients comprising the TMR revealed that 41.9% of the perchlorate came from corn silage, 22.9% came from alfalfa hay, and 11.7% was supplied by Sudan grass. It was demonstrated that the transfer of perchlorate from feed to cows was a significant source of perchlorate in subsequent milk samples.

Mean perchlorate concentrations measured in the blood, milk, urine, and feces of cows with calculated perchlorate intakes of 0.46 mg/day from feed and 0.03 mg/day from water were 0.24, 4.37, 3.68, and 5.84 ng/mL, respectively [1027].

There is an even higher concern about perchlorate accumulation in the milk of nursing human mothers. Measurements of perchlorate concentration in mother's milk indicated a mean level of 10.5 µg/L (range 0.6–92 µg/L) and a maximum level of 92 µg/L in 35 human milk samples from 18 states [1028, 1029].

Perchlorate concentrations in dairy milk from Japan are higher than values reported by the FDA in the US. Perchlorate concentrations in the Japanese samples ranged from 5.47 to 16.40 µg/L, with a mean value of 9.39 µg/L and a median value of 9.34 µg/L [994].

The concentration of perchlorate analyzed by using ion chromatography-electrospray tandem mass spectrometry in sewage sludge, rice, bottled drinking water, and milk collected in China was in the range of 0.6–380 µg/kg, 0.16–4.9 µg/kg, 0.04–2 µg/L, and 0.3–9 µg/L, respectively [995]. The results revealed that perchlorate pollution has been widespread in China, however, the sources are uncertain.

A study was conducted to evaluate perchlorate in the feed of cattle in dairy farms in the southwestern areas of the US [1030]. All feed products collected at dairies had detectable levels of perchlorate as analyzed using ion chromatography-tandem mass spectrometry. The calculated total perchlorate intake across dairies ranged from 1.9 to 12.7 mg/cow per day. Alfalfa products were the single most important source of perchlorate. The estimated perchlorate intake from drinking water ranged from 0.01 mg per cow per day and was generally less than 2% of the total perchlorate intake. The perchlorate content of milk ranged from 0.9 to 10.3 µg/L and was similar to levels reported by the FDA's TDS. The perchlorate content of milk was significantly related to the presence of perchlorate in feed but the variation of perchlorate in milk could not be explained by feed intake alone.

7.7 Ammonium Perchlorate Exposure in the Workplace

Worker monitoring in the workplace was mostly concerned with the thyroid gland response. Very little work has been done to monitor the other effects of long-duration

low-level exposure to AP on workers. The most likely path of ingestion would be through inhalation of perchlorate dust during grinding and powder transfer operations. For this reason, animal tests were performed where the lungs of test animals were dosed with AP solutions aerosols via inhalation (see Section 7.1.2).

Sixty-six workers occupationally exposed to AP dust from two factories, A and B, were selected as the exposed and 48 workers were selected as the unexposed control groups to study the effect of AP dust on the health of workers [1031]. Investigations on the working condition and sampling of dust in the workplaces and a special medical examination were conducted for both groups. This included occupational history, clinical manifestations, blood routine tests, hepatic and renal functions, indexes of thyroid hormones, spirometric tests, and chest X-rays. The average concentration of AP dust in the two factories were 2.53 mg/m^3 and 31.36 mg/m^3 , respectively. Dust concentrations in factory B were higher than those in factory A. The mean age and employment duration of the exposure group and the control group were 40.97 and 40.04 years, and 19.8 and 20.8 years respectively. The symptoms of respiratory and digestive systems (31.8% and 18.2%) in the exposure group were significantly higher than those in the control group (10.4% and 4.2%), ($P \sim 0.05$ or 0.01) respectively. The pulmonary function tests showed that Forced Expiratory Volume in One Second/Forced Vital Capacity (FEV1.0/FVC%) in the exposure group was significantly higher than that of the control group. One retired worker exposed to AP for 26 years in the exposure group, who had a diagnosis of pneumoconiosis, was found to have irregular opacities showing interstitial fibrosis under X-ray examination. It was concluded that long-term exposure to AP dust at high levels may cause respiratory system adverse effects and even induce pulmonary fibrosis.
